Preface

This volume serves to continue the subject matter of the earlier Chemistry of Petroleum Derivatives published in 1934. In some cases additional references to work published prior to that year have been included.

Little by little, as knowledge of the chemistry of various derivatives of petroleum expands, a comprehensive record of the work, other than that scattered information constituting the original papers, appears to be needed. This, then, is the purpose of the present volume.

The issuance of a book of the present size, so soon after the publication of the earlier volume, betokens to some extent the activity of investigators in this field. For this reason a revision of the 1934 volume was not attempted and the present publication is, as noted, essentially a continuation of the subject.

Since 1934 much material of importance to the petroleum chemist has appeared. Attention is especially directed to such chapters as those relating to sulphur (Chapter 19) and sulphonation (Chapter 46), dealing with utilization of by-products of refining; to polymerization (Chapter 26), a type of reaction applicable to the synthesis of motor fuels from gaseous hydrocarbons resulting from cracking or distillation operations; to detonation (Chapter 44), and to nitration (Chapter 47). In view of its growing importance to the petroleum industry a section treating the subject of thermodynamics has been included as Chapter 54.

A chapter has been added on the chemistry of asphalt and also one on a topic which perhaps at present is of less interest to the United States than to certain countries devoid of sources of petroleum; namely, to the production of hydrocarbons by treatment of carbon monoxide with hydrogen. Explanations or apologies, if any are needed, for discussing the subject here are that, despite our present abundant supplies of petroleum, there must needs come at some distant day a time when exhaustion of sources of petroleum will make inevitable a drastic survey of and search for other means of procuring liquid fuels. Numerous variations of carbon monoxide hydrogenation are known which result in a multiplicity of products. These modifications and others yet to be found may alter the aspect of petroleum chemistry. The search for new anesthetics has led many investigators to carry the hunt into the hydrocarbon field which serves to explain the presence of a new Chapter 53 on Petroleum Hydrocarbons in Anesthesia.

Chapter 1

Chemical Nature of Petroleum and Natural Gas. Pure Hydrocarbons from Petroleum

Petroleum is found all over the world, although both the quantity and the character of the oil differ enormously from place to place and even from diverse strata at the same location.[1] Crude petroleum may vary from a light gasoline to a heavy pitch, and in some instances wells only yield gaseous petroleum in the form of natural gas. However, the main producing countries in the world are, in the order of decreasing production, United States, Russia, Venezuela, Persia and Rumania. In Table 1 are given details of the total world's production of petroleum for the years 1930 to 1935.

TABLE 1. *World Production of Petroleum, 1930-35, by Countries, in Thousands of Barrels.*

Country	1930	1931	1932	1933	1934	1935
United States	898,011	851,081	785,159	905,656	908,065	993,942
U.S.S.R.	125,555	162,842	154,367	154,840	174,318	176,688[a]

In the United States, which is still by far the most important producing country in the world, there was a three-fold increase of production for the period 1920-1934 over 1901-1919 despite reduction of 13.4 per cent in the number of wells drilled.[3] While the average production per well drilled has increased from 925 cubic meters (for 1857-1900) to 6128 cubic meters (for 1920-1934) largely as the result of improved technique, there has been an upward trend in the number of dry wells. This fact indicates the increasing difficulty of discovering new producing horizons in spite of improvements in drilling practice. The economic and political factors which have played a prominent role in directing the development of the petroleum industry in the United States and other countries have been examined by Leupold.[4]

Production of petroleum in the U.S.S.R. increased 515 per cent during the period 1920-1931 and was 11 per cent of the world's total in 1934. Leupold states that the situation in Russia is still inferior to that of other main producing countries and that considerable waste of petroleum resources occurs. Russian exports of petroleum have decreased considerably since 1932 as a result of unfavorable conditions of production and refining, increased domestic consumption and economic and political difficulties.

The Venezuelan oil industry is largely controlled by certain international groups, particularly the Standard Oil subsidiaries, which, in view of the possible diminution of U.S.A. oil reserves, have striven to secure extra supplies in other regions.

In view of the enormous, and increasing, production of crude petroleum, the question of the total available resources of the United States is of major importance. Although there is always the possibility of ultimate exhaustion of petroleum resources, past estimates of such have invariably proven far too low, largely as a result of improved drilling technique, especially that of deeper wells. In the period 1922-1934, the crude oil reserves of the United States have increased from 5000 million barrels to over 13,000 million barrels in spite of the fact that production during that period totaled 9782 million barrels. In the face of a constantly increasing consumption of petroleum products, the visible supplies in the United States, obtainable by methods within the range of present production costs, have increased from 11 years' supply in 1922 to 15¼ years' supply at the rate of consumption at the end of 1933.[5] It must be remembered, also, that the 13,250 million barrels of producible oil estimated to have existed in the United States at the beginning of 1934 represent but a fraction of the ultimate total oil reserves of that country. There are still practically no completely exhausted oil areas in the United States, and the development of deeper drilling is opening up oil-bearing strata which are much more prolific than the shallower sands previously exploited. In the light of evidence available in 1934, the estimate that no shortage of oil will occur for at least 25 years[6] does not seem unduly optimistic. However, a more pessimistic view of the situation has been adopted by Brooks.[6a] He believes that the statement of oil reserves in terms of a number of years is misleading as indicating that no concern need be felt until the end of that period; whereas, fresh supplies of considerable magnitude will be needed in a relatively shorter period if the present production level is to be maintained. Brooks considers it probable that at some future period the cost of production of petroleum will tend to increase, and a point will be reached when certain substitutes (including shale oil or oil from the hydrogenation of coal) will begin to compete and check the rising price of natural oil.[7]

Improvements in operating technique have rendered possible the drilling of wells as deep as 11,380 feet, thus making available oil reservoirs previously inaccessible. The elimination of crooked-hole drilling has been an important factor in reducing waste. Other improvements include deep-well pumping, rendering possible the recovery of oil from depths previously considered to be beyond the reach of the pump, as well as the restoration and maintenance of pressure on oil sands with stripped natural gas or air.[8] Older methods are shooting with nitroglycerin and the application of vacuum to wells. Flooding oil sands with water is also effective in some fields in increasing production more than tenfold.[9] An interesting procedure applicable to limestone formations consists in pumping aqueous hydrochloric acid (in the presence of an inhibitor to minimize pipe-line corrosion) into the sand to increase porosity. This method, which is usually termed acidation, caused an average increase in production (for approximately 3000 acidized wells) of about 448 per cent. Furthermore, a number of wells previously abandoned as non-profitable have been rendered productive in this manner.[10]

NOMENCLATURE

As an aid to understanding the many terms applied to petroleum or its distillates, Table 3 (page 11) includes the synonyms often employed in the United States, Germany, England and France.[13]

GENERAL CHEMICAL CHARACTER OF CRUDE PETROLEUM

Crude oil consists essentially of a complex mixture of liquid and solid hydrocarbons, often containing dissolved gaseous hydrocarbons, together with smaller proportions of organic sulphur and nitrogen compounds. Oxygen-containing substances which may be present include organic acids (so-called naphthenic acids), small quantities of phenols and dissolved carbon dioxide. The carboxylic acids appear to be mainly derivatives of mono- and bicyclic naphthene (or cycloparaffinic) hydrocarbons, particularly cyclopentanes, although the higher straight-chain fatty acids have also been found.[14] As it issues from the well, crude petroleum is often associated with much water, usually containing dissolved inorganic materials. In some cases, relatively stable emulsions of oil and water are obtained. To reduce the aqueous content of the crude oil to pipe-line specification of 2 per cent or less, it is necessary to break such emulsions. The action of heat with or without the application of pressure is often employed, although chemical

Benzole	Benzol Motoren-Benzol	Benzole	Benzole
Spirit	Alkohol, Sprit Äthylalkohol	Alcoholic spirit	Benzole moteur Alcohol

or electrical precipitation is also used.[15] The inorganic materials which may be present in crude oil are considered later.

It is interesting to note that, although the chemical nature of many sulphur compounds and some nitrogen bases in distillates has been clearly established, little is known of the character of such compounds in crude undistilled petroleum. Although, for example, certain Californian petroleums of relatively high nitrogen content contain no basic materials capable of extraction with aqueous acids, their distillates furnish appreciable quantities of such bases. This has been attributed to the breaking down, or partial decomposition, of more complex nitrogen-containing bodies at distillation temperatures.[16] Similar observations have been made in the case of the sulphur and oxygenated organic constituents. Thus, Pyhälä[17] showed that some fractions derived from Russian petroleum contained about 12 times as much naphthenic acids as the undistilled crude oils. Whereas relatively simple organic sulphur compounds are found in distillates, and particularly cracked distillates, these are not present in the parent petroleum. In this connection, Kewley[18] reports that crudes, relatively rich in sulphur compounds, yield about 35 per cent of sweet-smelling liquids free from corrosive sulphur, if vacuum distilled below 140°C. At this temperature, however, decomposition of some of the unstable thio-compounds in certain crudes begins to occur. It is suggested by von Braun[19] that the nitrogen bases are formed by decomposition of albuminous substances in the crude. Under such circumstances no correlation appears possible between the composition of the sulphur- and nitrogen-containing bodies of distillates and the character of the crude oil from which they are derived.

---

[15] Some reagents for breaking oil and water emulsions are discussed in Chapters 46 and 48.

The important observation has been made by Treibs[20] that crude petroleums, as well as asphalts and oil-shales, contain detectable amounts of porphyrins, presumably derived from chlorophyll-containing materials. The presence of complex compounds of porphyrins with vanadium or bivalent iron in petroleum and bituminous extracts has also been demonstrated by Treibs.[21] It is significant that the California petroleums which yield fractions containing nitrogen bases are also relatively rich in chlorophyll porphyrins. The presence of optically active constituents in crude petroleum has long been known.[22]

CLASSIFICATION OF PETROLEUMS

The older methods of classification of crude oils into various basic types has for some time been considered inadequate and a new scheme, in which nine possible types of petroleum are recognized, has been outlined by Lane and Garton.[23] The basis of the new arrangement is the boiling point-gravity curve of the sample under investigation. Distillation up to 275°C. is carried out at atmospheric pressure and then continued at 40 mm. pressure. The observed gravities of two key fractions, namely, (1) that boiling at 250-275°C. at atmospheric pressure, and (2) that boiling at 275-300°C. at 40 mm. absolute pressure, are used to evaluate the base of the crude oil. Thus, if the A.P.I. gravity of the first key fraction is 40° or lighter, the lower-boiling fractions would fall in a paraffinic class. If it is 33° or heavier, they are naphthenic. If it is between 40 and 33°, lighter fractions are intermediate in type. Should the A.P.I. gravity of the second key fraction be 30° or more, then the higher-boiling portions are considered as paraffinic. When the gravity of this second fraction is 20° A.P.I. or less, then the higher-boiling distillates are assumed to be naphthenic. On the other hand, a gravity of 20 to 30° A.P.I. denotes the heavier portions to be intermediate. The following types are distinguished.

1. Paraffin base: distillates paraffinic throughout.
2. Paraffin-intermediate base: light fractions paraffinic, heavy fractions intermediate.
3. Intermediate-paraffin base: light fractions intermediate, heavy fractions paraffinic.
4. Intermediate base: distillates intermediate throughout.
5. Intermediate-naphthene base: light fractions intermediate, heavy fractions naphthenic.
6. Naphthene-intermediate base: light fractions naphthenic, heavy fractions intermediate.
7. Naphthenic base: distillates naphthenic throughout.

8. Paraffin-naphthene base: light fractions paraffinic, heavy fractions naphthenic.
9. Naphthene-paraffin base: light fractions naphthenic, heavy fractions paraffinic.

In another scheme of classification elaborated by Sakhanov and Virabyantz[24] and based on the relative proportions of paraffin, naphthene and aromatic hydrocarbons in various fractions, the following six types are defined:

1. Methane base.
2. Naphthene base.
3. Methane-naphthene base.
4. Aromatic base.
5. Methane-naphthene-aromatic base.
6. Naphthene-aromatic base.

HYDROCARBON CONSTITUENTS

As previously mentioned, the preponderating constituents of all petroleums are hydrocarbons. These may vary from gases or volatile liquids to heavy pitches, and consist of paraffins, naphthenes, aromatics, and polynuclear naphthenes and polynuclear aromatics. Unsaturated hydrocarbons, such as olefins, apparently are not found in undistilled crude oils. A very large number of chemical individuals are usually present even in a distillate of relatively narrow boiling range. Furthermore, crude oils display great variations in distillation data and general physical properties as well as in the chemical compositions of similar fractions.

The widely different proportions of paraffins, naphthenes, aromatic hydrocarbons, wax and asphalt in some petroleums, as reported by Stadnikoff,[25] are summarized in Table 4. Paraffin hydrocarbons are the sole constituents of the gaseous and volatile liquid portions of crude petroleums, at least up to and including those components having four carbon atoms per molecule. In many instances, such aliphatic compounds are present in large amounts in all fractions. The higher members are solids and are found as paraffin wax, petrolatum and ceresin in the higher-boiling fractions of many crude oils.

TABLE 4.—*Average Composition of Typical Petroleums.*

Type of Crude	Solid Paraffin Per Cent	Resins and Asphaltene Per Cent	Composition of 250-300°C. Fraction			Specific Gravity of Residue Boiling Over 300°C.
			Paraffins	Naphthenes	Aromatics	
Paraffin	1.5-10	0-6	46-61	22-32	12-25	0.897-0.929
Paraffin-naphthene	1-6	0-6	42-45	38-39	16-20	0.897-0.908
Naphthene	Trace	0-6	15-26	61-76	8-13	0.895-0.912
Aromatic-naphthene	0.5-1	0-10	27-35	36-47	26-33	0.921-0.949
Aromatic-paraffin-naphthene	0-0.5	0-20	0-8	57-78	20-35	0.950-0.970

The simple naphthene hydrocarbons in petroleum belong to the cyclopentane and cyclohexane series, while polycylic hydrocarbons of both types probably exist in the higher fractions. The relative proportions of cyclopentanes and cyclohexanes in various Russian straight-run gasolines have been determined by Sakhanov, Doladugin and Egorova.[26] All the crude oils examined, with a single exception, had a maximum content of cyclohexane hydrocarbons in the fraction boiling at 95-122°C.

[33] Values from "International Critical Tables," McGraw-Hill Book Co., Inc., New York and London, 1926, Volume I. High molecular weight paraffin hydrocarbons have been isolated in the products obtained by the Kogasin synthesis. For their physical properties, such as melting points, see Chapter 52.

Maman[34] and Whitmore and Laughlin,[35] respectively. The boiling points of the normal paraffin hydrocarbons are correlated by Cox[36] and Wakeman.[37] Calingaert and Hladky[38] summarized the data on the molecular volumes of the paraffin hydrocarbons. The change in ultraviolet absorption resulting from the alteration of mineral oils, and the rotary dispersion of a number of oils have been studied.[38a] The heats of combustion of ethane, propane, butane and pentane have been determined by Rossini[39] who later made a similar determination for isobutane.[40] Specific heats of pure liquid hydrocarbons and petroleum fractions are reviewed by Gaucher,[41] and the total heats of pentane and paraffinic naphtha under pressure have been determined by Pattee and Brown.[42] Physical properties of a number of higher paraffin hydrocarbons (C_{20}-C_{40}) have been determined by Ivanovszky.[43] Phase equilibria in various hydrocarbon systems, including specific heat measurements, have been studied by Lacey and his collaborators.[44] The viscosity of solutions of the higher paraffins have been measured by Staudinger and Staiger[45] and by Meyer and van der Wijk.[46] Sage, Sherborne and Lacey[47] determined the viscosities of solutions of ethane and *n*-butane in crystal oil.[48] Measurements of the boiling points and ultraviolet absorption of cyclopropane and propene have been made by Ashdown, Harris and Armstrong.[49] The density of liquid propene has been ascertained by Pall and Maass.[50] Some data concerning methyl nonanes has been obtained by Calingaert and Soroos;[51] and the experiments of Kassel[52] indicate the values for the vapor pressures of the xylenes and mesitylene. Several properties of series of hydrocarbons have been contributed

THE ORIGIN OF PETROLEUM

Among the older views of the origin of petroleum, the theory of the heat decomposition of organic remains in the sedimentary rocks has long been considered possible. This so-called destructive-distillation theory was first suggested by the experiments of Warren and Storer[59] in 1863 and later by Engler[60] in 1888. Fatty oils of marine origin were believed to be the raw materials in the pyrogenesis of mineral oils. Later Seyer[61] advanced the suggestion that petroleum is formed from fatty acids of animal or vegetable origin by slow cracking at high pressures and comparatively low temperatures. One important implication of Seyer's theory is that dense saturated molecules of low hydrogen-carbon ratio, such as polycyclic naphthenes, should be produced to a greater extent with increasing time, temperature and pressure.

[58a] A discussion of boiling-point calculations based on known boiling points of related or analogous compounds or of decomposition products is given by K. Billig, *Ber.*, 1937, **70**, 157.

However, a considerable body of data has been accumulated which would seem to support very strongly a low-temperature origin of petroleum.[62] The evidence, though circumstantial, is both chemical and geological and may be briefly summarized as follows. From the chemical viewpoint, the total absence, in petroleum and natural gas, of such typical products of thermal decomposition as hydrogen, carbon monoxide and olefin hydrocarbons, is in favor of a low temperature origin. More convincing is the existence in crude oil of certain complex sulphur, nitrogen and oxygenated organic substances readily decomposable by heat treatment, as well as of optically active constituents whose rotation would most certainly have been destroyed by prolonged exposure to even moderate temperatures.[63] Chlorophyll porphyrins, substances readily decomposable at relatively low temperatures, have also been found in many petroleums by Treibs.[64] It might be argued that some of these thermolabile substances could be formed by processes operating subsequently to the original destructive distillation, but such an explanation appears improbable. According to Brooks,[65] the presence of chlorophyll porphyrins in crude oil is an indication of (a) a low-temperature history, (b) the derivation of petroleum from, or association of the original source material with, chlorophyll-bearing plant life, probably marine algae, and (c) anaerobic conditions during the deposition of the original source material.[66]

It is a logical consequence of the destructive distillation hypothesis that, with increasing age and depth, petroleum should tend to become more and more naphthenic and heavy in character, while the younger deposits should be paraffinic. Although no entirely consistent relation has been discovered between petroleum composition and the age or depth of the deposit, the available data do not seem to be in accord with the demands of the thermal decomposition theory. From a study of the A.P.I. gravities and compositions of petroleums of different ages and depths in the Gulf Coast area, Barton[67] observed a progressive alteration of these properties with depth. Naphthenes and aromatic hydrocarbons occur to the greatest extent in the younger and shallowest Gulf Coast deposits, while the older and deeper ones are lighter and more paraffinic. This is in direct opposition to the demands of the theory. Seyer[68] emphasizes that from the chemical point of view the asphaltic and cyclic hydrocarbons must come from the paraffin hydrocarbons and not the reverse. For example, if A, B and C represent, respectively, the youthful, mature and old age stages in the life history of a petroleum, or, respectively, oils of young, middle and old geologic ages, then the base of A should be paraffinic, of B, mixed paraffinic and asphaltic, and of C, asphaltic. In support of this theory, the progressive change from naphthenic to paraffinic type with increasing age and depth does not appear to hold for certain other locations, including the fields of Wyoming[69] and California.[70] Details of the variation in properties of German petroleums at different depths of the same geological formation, as well as from different formations, have been supplied by Steinbrecher and Stutzer.[71] Pratt[72] has suggested that petroleums are progressively hydrogenated (to yield lighter and more paraffinic products) by hydrogen derived from methane, but the great stability of the methane molecule militates against the view.

FIG. 1A.—Pressure Stills.

It has been shown that the available chemical evidence, when considered as a whole, favors a low temperature history for petroleum which, however, is even more strongly supported by the geological data. Thus, Illing[73] states that the geological evidence demands a theory of petroleum origin almost contemporaneous with the sediments, and not, as the distillation theory indicates, as a later process of metamorphism. Views up to 1931 regarding source beds for petroleum have been discussed by Snider[74] and also by Trask and Hammar.[75] The temperatures observed in oil-bearing strata are all relatively low, bottom hole temperatures in some of the most prolific fields yielding oil from geologically younger sands being not in excess of 100°F. The rise in temperature with increasing depth is very gradual (being 1°F. per 52 ft. in Fullerton, California, and 1°F. per 70 ft. in Ozona, Texas). Temperatures noted at depths around 7000 ft. varied from 150°F. to 170°F.[76] Moreover, the geological evidence is in harmony with the view that the present observed temperatures must be near the maximum over the geological epoch during which petroleum could have been formed. This position has been summed up by McCoy and Keyte[77] with the statement that most of the known oilfields were undoubtedly formed at temperatures below 140°F. McCoy concludes that from evidence in another of his papers,[78] it is not very probable that oil accumulation has necessitated 60 million or more years to have been accomplished.

The chemical and geological evidence is in agreement with the view that petroleum is the result of low temperature anaerobic fermentation of organic matter, deposited in sediments as solid or semi-solid material. Unfortunately, very few attempts have been made to obtain experimental evidence as to the rôle of bacteria in petroleum formation, especially under alkaline anaerobic conditions. Taylor's[79] work concerned the slow anaerobic degradation of fatty oils and acids under sodium clay.[80] He found that triacetin under these conditions yielded methane alone, while gaseous paraffins were produced from tributyrin. Stearic and palmitic acids were slowly attacked, but the products were not examined. At present the depths in the sediments at which bacterial action ceases is in dispute, but the vertical distribution of bacteria in marine sediments has been investigated by ZoBell and Anderson.[81]

The principal types of organic substances which need to be considered as possible main source materials for petroleum formation in sedimentary rocks are cellulose, proteins, lignins, oleo-resins, waxes and fatty oils.[82] Of these, lignins, oleo-resins and waxes are resistant to bacterial action. Proteins, fatty oils and cellulose are decomposable by anaerobic bacteria, the latter type furnishing methane almost exclusively. Brooks,[83] from a detailed survey of the available evidence, concluded that the fatty oils are still to be regarded as the most likely source materials for petroleum formation.

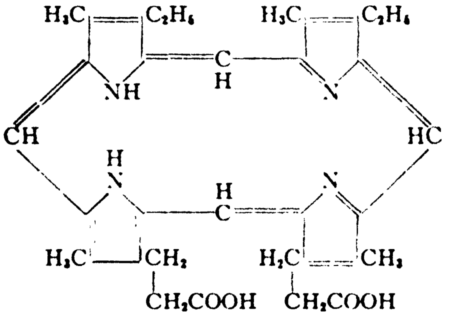
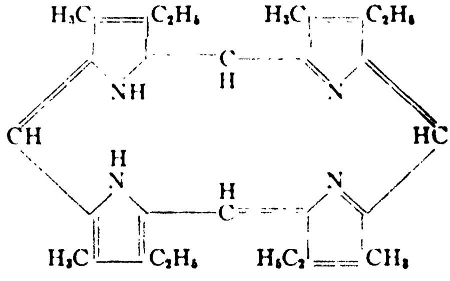
triassic[84] and the further identification[85] in this isolated portion of mesoporphyrin (formula III) and meso-ätioporphyrin (formula IV) led Treibs[86] to the conclusion that petroleum probably had its genesis from chlorophyll containing material such as the shallow-water plankton.



III.



IV.

Fish remains are considered by Henderson[87] to be insufficient in amount to account for the large quantities of petroleum occurring in some formations. The development of oil through a fossil-resin stage from the same source materials as those yielding coal has been suggested by Briggs.[88] Fester and Cruellas[89] assume that petroleum is derived from the fatty material remaining after the bacterial decomposition of marine flora and fauna in tropical climates; whereas, in colder climates, cellulose and lignin did not undergo complete decomposition and varieties of coal were the ultimate results. Colloidal vanadium sulphides, which are present in South American petroleums, probably exert a catalytic action on the processes of organic change, according to Fester and Cruellas.[90]

If anaerobic decay of organic material in sediments is the origin of petroleum, it might be expected that protopetroleums in transition stages will be found in geologically recent strata in the form of solid or semi-solid material. Brooks[91] suggests that such material will possibly consist of a mixture of hydrocarbon oils together with polymerized fatty or naphthenic acids.

Synthetic oils similar to petroleum have been prepared by Berl and Biebesheimer[92] by the hydrogenation of the product obtained by digesting cellulosic material with aqueous alkalies at 310-330°C. and 180-200 atmospheres pressure. They proposed the theory that petroleum had its origin under similar conditions and that asphalt was formed if reaction took place at shallow depths where oxidation could occur.

Careful fractionation of Hodonin (Czechoslovakia) crude oils at absolutely constant pressure has been found by Wenzel and Weiser[93] to yield maximum cuts corresponding to hydrocarbons having 15 and 20 carbon atoms per molecule in one case, and to those having 13, 15, 20, 25 and 28 carbon atoms in a second instance. A terpenic origin is suggested to explain this observation. Oxidation of one fraction, having the empirical composition of $C_{28}H_{46}$, with potassium permanganate in hot acetone furnished phthalic acid, from which it was concluded that the parent-hydrocarbon had the constitution o-$C_6H_4(CH_2C_{10}H_{19})_2$, the $C_{10}H_{19}$ radicals being naphthenic residues. Wenzel and Weiser suggest that such a compound could be formed from squalene by condensation of the latter accompanied by aromatization and loss of two methyl groups. The results are interpreted as indicating the derivation of petroleum from marine plants.

NATURAL GAS

The production and utilization of natural petroleum gases is being carried out in many parts of the world, notably in Russia, Persia, Poland, Rumania, Germany, Italy and British India, but the industry has attained its greatest importance in the United States, of which Texas is the largest producer. The quantities produced in the United States in 1933 and 1934 were 1555 billion cu. ft. and 1770 billion cu. ft., respectively.[94] The present known natural gas reserves of the United States are reported sufficient to last for many years at the present rate of consumption. Thus, it is estimated that the Amarillo field of Texas will continue to supply gas at the present rate for at least 60 years. Of interest in this connection is the discovery of large reservoirs of natural gas in the deeper strata in northern Pennsylvania and New York, where pressures as high as 2250 pounds per sq. in. are encountered at depths of 4000-5000 ft.[95] In 1933 half of the natural gas produced in the United States was used as an industrial and domestic fuel and the remainder in the oil fields and for carbon black manufacture. In fact, the amount of natural gas consumed annually (at the 1933 rate) is equal in heating value to about 70 million tons of bituminous coal.

Natural petroleum gases consist essentially of a mixture of lower paraffin hydrocarbons as well as varying proportions of nitrogen, carbon dioxide and traces of rare gases such as helium. Hydrogen and carbon monoxide are uniformly absent. In the so-called dry gases, methane is the main hydrocarbon constituent, and the wet gases usually contain, in addition, appreciable proportions of the higher paraffins (ethane, propane, *n*-butane, isobutane, *n*-pentane, isopentane or neopentane). The wet gases are usually treated for the recovery of volatile liquid constituents—the so-called natural gasoline.[96]

[96] For a general discussion and classification of natural gases, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, 1934.

Isolation and identification of the various hydrocarbon constituents of natural gases are readily accomplished by low-temperature fractional distillation, a process which is now standardized as an analytical procedure. By this method, ethane, propane, *n*-butane and isobutane have been secured in pure condition from liquefied Polish natural gas by Kling and Wiecławek.[97] Wet gas from a well near Pittsburgh was found to contain benzene to the extent of nearly 18 parts per million.[98] The carbon dioxide content of natural gases is variable although in special cases it may be present as the preponderant constituent. Thus, wells delivering a gas containing 98.6 per cent of carbon dioxide with a remainder of nitrogen and helium and no hydrocarbons or hydrogen sulphide have been found in New Mexico and serve as a ready source of this dioxide.[99] According to Wittich,[100] such incombustible gases are being utilized in Mexico for power production by virtue of their high pressure, as well as in the manufacture of solid carbon dioxide. Gases of analogous characteristics have been obtained from wells in Colorado,[101] the composition of one being: methane, 0.52 per cent; ethane, 3.95 per cent; carbon dioxide, 92.14 per cent; oxygen, 0.09 per cent; nitrogen, 3.16 per cent; and helium, 0.14 per cent.[102] Large proportions of this dioxide and only small amounts of methane are present in the gases from borings in the Tuscan boraciferous regions of Italy.[103]

Although usually present only in traces, nevertheless helium does occur to the extent of 1.8 per cent in a natural gas from the Cliffside structure near Amarillo, Texas. Separation is effected by a process of fractional liquefaction (after removal of carbon dioxide) at a net cost of about 8.6 dollars per 1000 cu. ft. of helium produced.[104] The argon-nitrogen ratio in natural gases has been found by Geslin[105] to be less than for air, a fact which is attributed to dilution with nitrogen derived from the decomposition of animal and vegetable material. A method of determining helium and argon in natural gases has been described by Gerling.[106] Snow and Johnston[107] report that a sample of butane from an Oklahoma field contained 30 per cent more deuterium than corresponds with the content of this element present in ordinary hydrogen.

The compositions of a large number of natural gases (from different fields) have been determined,[108] including those from Germany,[109] particularly the Merihagen field,[110] Poland,[111] Austria,[112] France,[113] British India, Burma and Assam[114] and Russia,[115] especially those from the Grozny,[116] Apsheron[117] and Baikal Lake[118] districts.

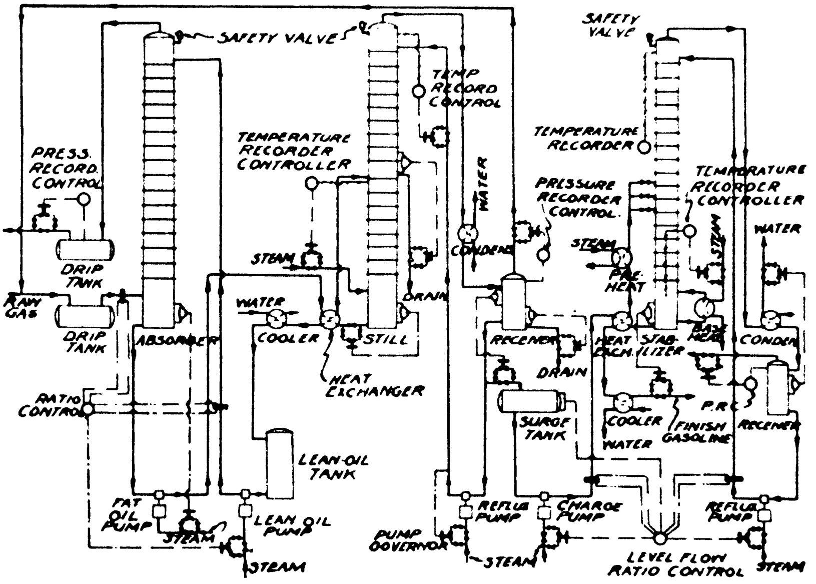
UTILIZATION

As already mentioned, the most important applications of natural gas are as a fuel for both domestic and industrial purposes and as raw material for the manufacture of carbon black.[119] Among other uses for which natural gas has been suggested are the preparation of halogen derivatives of methane, ethane, propane and pentane, monohydric alcohols, acetone, acetic acid and formaldehyde.[119a] In addition, the wet gases are usually treated for the recovery of natural gasoline and also of the so-called liquefied gases, propane and butane. Before these liquid and readily liquefiable constituents are separated, the gas is freed from hydrogen sulphide, usually by passage through a bed of iron oxide or by absorption in a solution of a suitable weak base.[120] Removal of liquid hydrocarbons can be effected either by compression, charcoal adsorption or by oil absorption, but the latter system is now generally employed. The charcoal adsorption process has,



Courtesy Industrial and Engineering Chemistry

FIG. 2—Flow Diagram of Stabilizing Unit of Natural Gasoline Plant. (G. A. Burrell)

since the advent of the stabilizer, lost the advantages it originally possessed over the rival methods of furnishing a gasoline of relatively low vapor pressure. Moreover, it also suffers from the disadvantages that charcoal is expensive, heat exchange is difficult and minute oil sprays cause a deterioration in charcoal activity. For these reasons oil absorption, in which the gas is washed with oil under pressure in bubble type absorbers, is favored in modern practice. The more volatile constituents, propane and butanes, of the resulting gasoline are removed in pressure fractionating columns, or stabilizers of the bubble type, and constitute the so-called liquefied petroleum gases. The developments and improvements for the 20 years prior to 1934 in the design of absorption plants have been described by Burrell[121] and by Kallam.[122] (See Fig. 2.) An account of the principles of design and operation of such plants has been supplied by Burrell and Turner.[123]

[120] Several methods for the elimination of hydrogen sulphide from gases are discussed in Chapter 19.

Propane and butane, now being used extensively in liquid form as fuel, are by-products of the stabilization of natural gasoline. The actual proportion of these hydrocarbons in the wild gasoline[124] depends primarily on the quantity of absorption oil employed per unit volume of gas washed.

The stabilizer is usually operated so as to eliminate all the propane and most of the butane from the wild gasoline. Pressure fractionating equipment is now available, capable of separating efficiently and recovering in pure form all hydrocarbons up to and including the pentanes in natural gas and natural gasoline.[125] In the usual mode of operation the raw distillate from the stabilizer passes through a preheater and heat exchanger to a butane column from which butane is extracted at the base, a mixture of propane and ethane constituting the overhead product. The latter passes to a high pressure column from which pure propane is withdrawn at the bottom and ethane as the overhead product. Working pressures are usually about 300-400 pounds per sq. in. on the butane column and from 400 to as high as 600 pounds per sq. in. on the propane column, depending upon the operating temperatures.

The importance of liquefied propane and butane is increasing rapidly, particularly as domestic and industrial fuels.[126] The production of these materials has increased from 222,000 gallons in 1922 to 48,173,000 gallons in 1934.[127] These figures do not include large quantities of these gases which are used at the place of production as raw material in the manufacture of solvents, or as refrigerants and fuels. Gases for industrial purposes are distributed principally in special tank cars, but with the development of high tensile strength sheets there has been an increasing use of trucks and trailers. "Bottled gas," distributed in many parts of the

United States is mainly propane (or propane and propene). In some instances, small quantities of butane may be present when its lower volatility does not necessitate the application of heat. Tentative specifications for some of these liquefied gas mixtures include the following.[128] Commercial propane shall consist of at least 95 per cent of propane plus propene and the residue (as determined by the mercury freezing test) shall not exceed 2 per cent by volume. Corrosive sulphur compounds shall be absent and the concentration of relatively inactive organic sulphur shall not exceed 15 g. per 100 cu. ft. of vapor. In the case of commercial butanes, the predominant hydrocarbons present should be butanes and butenes. The vapor pressure at 105°F. must not exceed 75 lbs. per sq. in. gage. Not less than 95 per cent of the material shall evaporate below 34°F. in the open cylinder weather test. Sulphur limitations are the same as for commercial propane, and freedom from entrained water is also necessary in each case. The product known as industrial propane usually consists of at least 70 per cent by liquid volume of propane (and propene). Industrial butanes containing 50 per cent of butane are also marketed.

FIG. 3.—Vapor Absorption and Stabilization Plant. High- and low-pressure absorbers equipped with internal coolers and gas-ratio controllers.

The largest use of bottled propane has been in kitchen ranges and water heaters, while butane has been predominant in the industrial field. However, propane has the advantages of low boiling point, high octane number, refrigeration qualities and value as a metal-cutting fuel.[129] The application of these gases in industrial furnace heating, particularly in the steel industry, has been described by Jamison and Bateman.[130] Some of the advantages are improved control both of temperature and atmosphere, reduced maintenance on furnace refractory and alloy parts and reduced scaling of product. The significance of propane and butane in the gas industry has been outlined by Brückner[131] who states that their low ignition velocities preclude their employment in welding. Cold enrichment of water-gas also is a possible application of such gases.

---

[128] W. H. Bateman, *loc. cit.* T. W. Legatski and W. Z. Friend, Meeting of Amer. Chem. Soc., Petroleum Division, San Francisco, Aug., 1935.

Both propane and butane possess certain advantages as a fuel in internal combustion engines, including high octane numbers, decreased oil consumption and carbon formation and high volatility, the latter property insuring uniform distribution in the cylinders. Yet, the general replacement of gasoline by liquefied gases as an automotive fuel as yet does not appear wholly feasible, since storing and distributing costs are high and special pressure fittings are necessary. However, possible applications are in large high-powered stationary engines or in rail cars and trains where high power output is demanded and high compression ratios are permissible.[132] According to Albright,[133] a fuel consisting of 80 per cent butane and 20 per cent propane and having an octane number of 100 is being used on heavy duty commercial units. The fuel is reduced to atmospheric pressure through two regulators, and carburetion is effected in the original carburetors or in specially designed mixing chambers. The question of the use of butane as an automotive fuel has been also discussed by Barnard.[134] He concludes that this material cannot be economically adapted for small units but is suitable for railway service. In fact, this hydrocarbon was first used successfully as fuel in 1930 by the Los Angeles Railway Company with advantages which included better lubrication, less carbon deposition and diminished valve pitting and burning.[135] The development of butane as a rail car fuel has been analyzed by Stockman.[136] Fuel consumption per mile is higher with butane than with gasoline, but this is said to be more than balanced by the increase in power and speed.[137] The possibility of using propane and butane in combustion motors has received particular attention in Germany, where a liquefied gas containing 60 per cent of the propane and 40 per cent of butane (called Deurag) is marketed for this purpose.[138] One important application of these gaseous fuels is in airships. Thus, mixtures of hydrogen and propane or hydrogen and butane having the same density as air are proposed by de

Florez[139] for the purpose. It is pointed out by Alden[140] that an increase in the butane content of gasoline would effect several economies, but such increase is limited by the question of vapor lock which may require redesigning of the engines. Other possible industrial applications of liquefied butane and propane are in the cutting of steel (in place of acetylene), the brazing of metals and alloys, the welding of aluminum and lead burning,[141] as well as in refrigeration. Other hydrocarbon gases, including methane[142] and coal gas,[143] have been considered as motor fuels. Such gases, as well as those previously discussed, need to be stored under high pressures in cylinders, which introduces the grave drawback of much extra weight.[144]

FIG. 4—Debutanizing Plant. Daily capacity 15,000 barrels of raw pressure distillate.

It has been shown by Hammerschmidt[145] that the lower paraffin hydrocarbons are capable of forming relatively high-melting solid hydrates with water vapor. The melting point of the mixed hydrates from a natural gas (in a transmission line) varied with the pressure from 34°F. at 110 pounds per sq. in. to about 60°F. at 800 pounds. This shows the importance of adequate drying of hydrocarbon gases in facilitating the handling and transport of such substances under pressure.

The moisture content of liquefied gases such as propane and butane also needs rigid control. One qualitative test for moisture involves the use of cobalt bromide.[146]

TECHNICAL TREATMENT OF CRUDE OIL

Separation of crude oil into component fractions involves distillation followed by refining of individual cuts and, possibly, cracking. Distillation is now carried out in modern pipe stills[147] with capacities up to 20,000 barrels per day. In such operations the oil is preheated continuously in a coil to a temperature sufficiently high to effect vaporization and is then passed into a bubble-plate fractionating tower, the different fractions being simultaneously withdrawn at various points in the tower. In some installations, such as that shown diagrammatically in Fig. 5, the crude is distilled in the first stage at about atmospheric pressure, taking off gasoline, kerosene and gas oil. The residue is subsequently distilled under reduced pressure to furnish lubricating oil fractions. In other installations the entire procedure is carried out in one stage, the lubricating oil being also taken as an overhead product. Indirect heating through the medium of vapors of biphenyl, mercury, or other high-boiling substances is sometimes employed to obviate local overheating and resulting decomposition. Typical fractions are: gasoline, having final boiling (or end) point of about 400°F.; kerosene, end point of 490°F.; light gas oil, final boiling point of 540°F.; mineral seal oil, heavy gas oil, wax distillate and cylinder stock. Enormous technical advances in the large scale distillation of petroleum have been made in the last decade, and the old horizontal shell still, running crude to coke, fuel oil, or lubricating oil, has become of limited value owing to the more economical pipe still.[148]

Refining operations which are used for the subsequent treatment of the individual petroleum fractions are, for the most part, outside the scope of the present work. However, the present chapter contains a brief summary of the salient features of a few solvent extraction processes for the improvement of the higher petroleum fractions (including kerosenes and lubricating oil distillates), since they involve a partial segregation of oil fractions into hydrocarbons of different types. The refining methods of the petroleum industry, which are discussed elsewhere,[149] have for their object the production of petroleum fractions (i.e., complex hydrocarbon mixtures) having properties specially suited for their applications rather than for the separation of pure hydrocarbons or of mixtures of chemically-related hydrocarbons.[150]

STRAIGHT-RUN GASOLINES

Straight-run gasolines consist essentially of a mixture of paraffin, naphthene and aromatic hydrocarbons, unsaturated hydrocarbons being usually present only in small amounts.[151] The relative proportions of these various classes of hydrocarbons in gasolines from different crude oils vary widely.[152] As a rule, however,

The usual analytical methods suffice to give a rough quantitative picture of the relative proportions of paraffinic, naphthenic and aromatic hydrocarbons in gasolines. The procedure generally adopted involves removal of the aromatics by the aid of sulphuric acid (which exerts a preferential solvent action on these hydrocarbons), followed by a determination of the aniline point of the remainder to ascertain the proportions of paraffinic and naphthenic constituents. The detection and isolation of individual hydrocarbons from gasoline fractions is, however, a much more complicated task and demands elaborate equipment and careful technique.[153]

Prolonged fractionation into relatively narrow cuts is generally adopted as preliminary to the isolation of individual hydrocarbons from gasolines. Much information has been accumulated by the investigations of the Bureau of Mines and A.P.I. Research Projects, and a large number of pure hydrocarbons have been isolated from the gasoline fractions of Mid-Continent crudes.[154] Distillations were carried out in a bubble-cap fractionating column fitted with automatic pressure control. Separations were assisted by the use of reduced pressure (down to 0.0001 mm. mercury) owing to the fact that the vapor pressure-temperature curves of a paraffin and naphthene, normally boiling at similar temperatures, cross each other so that the relative volatilities of these two classes of hydrocarbons can be varied by altering the pressure.[155]

Two types of constant-boiling mixtures were encountered in this work. A group of hydrocarbons having nearly identical boiling points often form a substantially constant-boiling mixture of the "true-solution" class. Such a combination cannot be separated by fractionation. Other types were the azeotropes, having a minimum or maximum boiling point and always associated with the presence of aromatics. Removal of the latter hydrocarbons obviated this formation.[156] In order to break up these constant-boiling mixtures, various methods were employed, including fractional crystallization with or without added solvents, fractionation by extraction with aniline or liquid sulphur dioxide, distillation in the presence of an alcohol or acetic acid or at low pressures and chemical methods such as nitration and sulphonation.

Aromatic hydrocarbons can be separated from gasolines or close-boiling distillates of gasolines by the use of certain selective solvents, such as liquid sulphur dioxide[157] or β,β'-dichlorodiethyl ether.[158] Extraction with 97-99 per cent sulphuric acid is said to eliminate about 90 per cent of the aromatic compounds of which 50-90 per cent can be recovered by dilution of the acid layer and distillation with superheated steam at 140 to 210°C.[159] Fractionation into narrow cuts followed by nitration or bromination has been employed by Cosciug[160] in the examination of the aromatic hydrocarbons in Rumanian petroleums. Separation of pure benzene from a narrow fraction of Shukkoko (Japan) crude oil has been achieved by Mizuta[161] by repeated fractionation and crystallization at low temperatures. It has been found by Mair and White[162] that silica gel exercises a preferential adsorptive power towards aromatic and olefinic hydrocarbons, which can thus be removed from paraffin and naphthene hydrocarbons. The gel shows a slight tendency to adsorb naphthenes in preference to paraffin hydrocarbons, while a slight separation of *n*-paraffins of different molecular weights was also observed. This same agent has been employed to remove aromatic hydrocarbons from ethylcyclohexane isolated from petroleum.[163] The use of various adsorbents in the purification and refining of petroleum products has been investigated by Dubrisay.[163a]

Segregation of naphthenes from paraffin hydrocarbons is a matter of considerable difficulty. Certain selective solvents have been suggested, some of which are discussed later in this chapter. According to Galle, Klatt and Friedl[164] no separation is effected by the use of β,β'-dichlorodiethyl ether. Low temperature fractional crystallization from a mixture of liquid propane and methane[165] and also from dichlorodifluoromethane[166] has been advocated particularly for the isolation of pure naphthenes from gasoline fractions also containing paraffins. Glacial acetic acid has been employed effectively in operations involving fractional distillation.[167] Five- and six-membered naphthenes in straight-run gasolines can be identified and determined by catalytic dehydrogenation (to the corresponding aromatics) in the presence of platinum or palladium, according to the Zelinskii method.[168] An analogous procedure has been applied to various fractions of Surakhany gasoline by Zelinskii and Shuykin,[169] using nickel and platinum catalysts.

Paraffin Hydrocarbons in Gasoline Fractions. For the isolation of normal paraffin hydrocarbons from admixtures with isoparaffins, advantage is often taken of the superior chemical activity of the latter (particularly those containing a tertiary carbon atom) towards such reagents as chlorosulphonic acid, antimony pentachloride and nitric acid. The isolation of the normal paraffins, hexane to decane, from fractions of various Russian gasolines was accomplished by Virobyantz and Gabrielyantz[170] by employing 98 per cent sulphuric acid (to eliminate more reactive hydrocarbons), followed by repeated treatments with chlorosulphonic acid at temperatures ranging from 55°C. in the case of hexane to 105°C. for octane, nonane and decane. In the preparation of *n*-heptane from a shale oil gasoline, Orlov and Ivanov[171] employed antimony pentachloride, a reagent known to attack tertiary paraffins at ordinary temperatures. The same reagent has been employed to identify tertiary paraffins in Surakhany straight-run gasoline, but the reaction is said to be inapplicable for exact analysis.[172]

A method for the examination of gasolines by the aid of their Raman spectra[173] has been proposed by Andant.[174] This method does not permit the immediate identification of all the hydrocarbons present in a gasoline, owing to the similarity of the spectra of hydrocarbons of the same group. However, it often leads to a precise knowledge of the chemical groups present. By applying this procedure, Andant[175] examined several gasolines and obtained evidence that paraffins, naphthenes and aromatics were present, the proportions depending upon the particular gasoline considered. The near infra-red absorption spectra of a number of pure hydrocarbons have been studied by Liddel and Kasper.[176]

Of the paraffin hydrocarbons, the following have been shown to be present in a distillate, boiling between 55 and 145°C., of an Oklahoma petroleum: 2,3-dimethylbutane, 2- and 3-methylpentane, *n*-hexane, 2,2-dimethylpentane, 2-methylhexane, *n*-heptane, 2-methylheptane, *n*-octane. From the portion boiling between 145 and 180°C. of the same petroleum, *n*-nonane and *n*-decane were isolated.[177] The normal paraffins from hexane to decane have been isolated from appropriate fractions of Grozny mixed-base and Maikop gasolines by Virobyantz and Gabrielyantz,[178] and *n*-hexane and *n*-heptane, with some cycloparaffins and aromatics, have been identified in Hodonin (Czechoslovakia) crude oil by Landa, Machacek and Mzourek.[179] By careful fractionation and examination of the various cuts, Tongberg, Quiggle and Fenske[180] have shown that Michigan straight-run gasoline contained a greater proportion of *n*-paraffins and aromatics than Pennsylvania straight-run gasoline. The latter, however, is richer in branched-chain paraffins. According to Leslie,[181] 2-methylheptane and iso-octane are present in a fraction (of a Mid-Continent petroleum) which boiled between 115 and 124°C. Nonane (and 2-nonene) has been isolated from a cut of Fushun shale oil distilling at 133-

[illegible] C.[182] 3,3-Dimethylheptane and 3,3-diethylpentane are believed to exist in minor proportions in this latter distillate. White and Rose[183] have utilized glacial acetic acid in the separation of an isononane from an Oklahoma petroleum by fractional distillation.

Naphthenic Hydrocarbons in Gasoline Distillates. The monocyclic naphthenes in straight-run gasolines are usually mixtures of both cyclopentane and cyclohexane hydrocarbons. Evidence for the occurrence of cycloparaffins with three- or four-membered rings is lacking although the presence of cycloheptane hydrocarbons in some petroleums has been inferred from spectroscopic data.[184] The relative proportions of cyclohexane and cyclopentane hydrocarbons in a number of Russian straight-run gasolines have been determined by Sakhanov, Doladugin and Egorova,[185] using the catalytic dehydrogenation method of Zelinskii. In practically all the crude oils investigated, the maximum content of cyclohexane homologues occurred in the fraction boiling at 95-122°C. The gasoline fractions of Baku crude oil contained up to 50 per cent of cyclohexanes, which was greater than that of cyclopentanes.

Zelinskii and Schuykin[186] observed that fractions of Surakhany gasoline (boiling between 75 to 105°C. and 105 to 125°C.) contained about 53 per cent (by volume) of hydroaromatic hydrocarbons which could be dehydrogenated (over nickel deposited on alumina) to aromatics. Higher-boiling cuts, up to 140°C., also possessed a large proportion of hexamethylene (and other naphthene or cyclane) derivatives. Analyses of the latter fractions, as given by these investigators, are in Table 7. The toluene fraction, boiling at 100.5-110.5°C., of Maikop gasoline was found by Maslov and Kozuireva[187] to contain 33 per cent of cyclohexanes and 21 per cent of cyclopentane hydrocarbons. Leslie[188] reports the presence of two octanaphthenes in the fraction of a Mid-Continent petroleum distilling between 115 and 124°C. In the portions of Ural (Perm) petroleum boiling at 150-240°C., examined by Zelinskii and Yur'ev,[189] the proportion of cyclohexane hydrocarbons was about the same throughout, but the content of saturated cyclic compounds increased with the boiling range.

TABLE 7.—*Analysis of Fractions of Surakhany Gasoline.*

	Per Cent by Weight			
B. P. of Fraction °C.	Aromatic Hydrocarbons	Cyclohexane Hydrocarbons	Other Cyclanes	Paraffins
118-120	About 1.0	56.2	15.5	27.3
120-124	1.7	56.9	15.7	25.7
124-130	4.0	54.3	20.0	21.7
130-140	5.0	44.6	23.2	27.2

Of the five-membered naphthenes, cyclopentane has been found in Hodonin

(Czechoslovakia) petroleum.[190] Methylcyclopentane and dimethylcyclopentane have been isolated from Oklahoma straight-run gasoline[191] and recognized in Montechino (Italy) crude oils.[191a] The nonanaphthene, boiling at 136.65°C., extracted from an Oklahoma crude oil by White and Rose,[192] is considered likely to be a cyclopentane derivative.

Cyclohexane has been identified as a constituent of the crude oil of Montechino[193] and of Mid-Continent petroleum.[193a] It is also present, along with methylcyclohexane and dimethylcyclohexanes, in Hodonin petroleum[194] and in Surakhany (Russia) straight-run gasoline.[195] The dimethylcyclohexane obtained by Leslie[196] by fractional distillation and crystallization of the fraction, boiling near 120.5°C., of a Mid-Continent petroleum was mainly the meta-compound admixed with a little of the para form. A portion of Surakhany gasoline boiling between 115 and 125°C. was stated to contain 1,2-, 1,3- and 1,4-dimethylcyclohexane.[196a] A fraction of Baku petroleum which boiled in the range of 135-138°C. was said to furnish 1,2- and 1,3-dimethylcyclohexane as well as 1-methyl-2-ethyl, 1-methyl-3-ethyl and 1,2,4-trimethylcyclohexane.[196b] Ethylcyclohexane has been obtained from the same petroleum by a laborious procedure involving repeated fractional distillation, crystallization from propane and methane, filtration through silica gel and distillation with acetic acid.[197] The existence of 1,3-5-trimethylcyclohexane in Hodonin (Czechoslovakia) oil is reported.[198]

Aromatic Hydrocarbons in Gasoline. Aromatic hydrocarbons so far identified in Mid-Continent straight-run gasolines are benzene, toluene, ethylbenzene, *o*-, *m*- and *p*-xylenes and the three trimethylbenzenes.[199] Benzene, xylene, mesitylene and naphthalene have been found in the gasoline fractions of Hodonin (Czechoslovakia) petroleum.[200] Benzene, which is also present in some Italian petroleums,[201] has been isolated in pure form from Schukkoko (Japan) crude oil by Mizuta[202] and from a Grozny petroleum fraction boiling below 105°C.[203] Fractionation of a toluene fraction of the latter petroleum in a discontinuous fractionating column furnished toluene of about 50 per cent purity. It was believed that a purity of 70 per cent should be possible with 25 actual plates.[204] The presence of

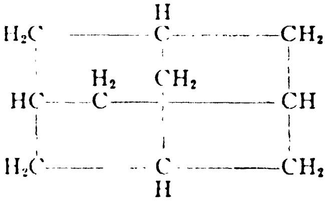
m-xylene in a low boiling cut of a Fushun shale oil has been shown.[205] Mizuta[206] has separated *o*- and *p*-nitrotoluene from mononitrotoluene prepared from the gasoline fraction of Shukkoko crude oil. Also, from the same crude, ethylbenzene and the three xylenes were isolated.[207] Cosciug[208] has identified the following aromatic hydrocarbons in the fraction, boiling at 40-200°C. at 27-28 mm., of Rumanian petroleum: toluene, the three xylenes, 1,3,5-trimethylbenzene, 1,3-methylethylbenzene, *ter.*-butylbenzene, pseudocumene, 1,2,3,4- and 1,2,4,5-tetramethylbenzenes. The distribution of aromatic hydrocarbons in several Rumanian gasolines has been studied by Cerchez.[209]

An interesting hydrocarbon, adamantane, has been isolated from Hodonin (Czechoslovakia) crude oil fractions. Its structural formula, shown below, indicates it to be probably the lowest member of a series belonging to the tricyclodecane group.[210]



KEROSENES

The most important characteristic of kerosenes is their burning quality, a property which is adversely affected by the presence of asphaltic compounds, sulphur and halogen compounds. An increase in the illuminating power of kerosenes results from increasing aromatic hydrocarbon content. Treatment of kerosenes for the removal of these deleterious constituents has been described by Critchley,[211] the usual refining agents being sulphuric acid or liquid sulphur dioxide. Fuming sulphuric is recommended for asphaltic kerosenes, but weaker acids are sufficient for the paraffin-base oils. In the Edeleanu process involving solvent extraction with liquid sulphur dioxide at low temperatures, the dioxide exerts a preferential solvent action on aromatic and unsaturated hydrocarbons as well as on sulphur compounds (including mercaptans, disulphides and cyclic sulphur-containing bodies). Most paraffin hydrocarbons are practically insoluble in this solvent. The color reversion often encountered in kerosenes may be caused by oxidation of phenolic constituents and probably cyclopentadiene and unsaturated naphthenes. In some instances, particularly with unrefined kerosenes, amino compounds may also be involved. The sulphur dioxide extract, obtained as described above, may be hydrogenated to furnish a solvent for insecticidal compositions.[211a] The extract, when freed from the dioxide, is said to have a solvent power of 2.3 per cent for rotenone and rotenoids. Hydrogenation is reported to increase the solvent action to 7.2 per cent.

The presence of naphthene hydrocarbons in kerosene distillates has been shown by the work of Wenzel and Weiser, previously mentioned. These investigators prepared cuts of narrow boiling ranges and corresponding to hydrocarbons having 13 to 28 carbon atoms per molecule, and studied the oxidation products therefrom. As pointed out before, Zelinskii[212] obtained evidence for the occurrence of cyclohexane derivatives (by dehydrogenation of kerosene fractions) and also of paraffins. The isolation of pseudocumene, mesitylene and hemimellitine from the sulphur-dioxide extract of kerosene (from Oklahoma crude oil) is described by Mair and Schicktanz.[213]

The kerosene fraction, boiling between 150 and 250°C., of a Ural crude oil has been shown by Zelinskii[214] to contain monosubstituted aromatic compounds in the 225-240°C. cut, but not any trace of decahydronaphthalene. Naphthalene and β-methylnaphthalene have been obtained from Rumanian oil fractions boiling between 100 and 112°C. by treatment with a concentrated ethereal solution of picric acid, causing the picrates of these hydrocarbons to be precipitated.[215]

HIGHER PETROLEUM FRACTIONS

Although the lubricating oil fractions of petroleum have received intensive study from the viewpoint of their physico-chemical characteristics, including viscosity-temperature relationship, oiliness and susceptibility to oxidation, very little advance has been made in the knowledge of their chemical nature. However, the preliminary results of an investigation of the characteristics of the hydrocarbons in lubricating oil fractions of Oklahoma petroleum is reported by Mair, Schicktanz and Rose.[216] The distillates were extracted with liquid sulphur dioxide, crystallized from ethylene chloride and fractionally distilled in order to separate asphaltic and resinous matter, wax and water-white fractions, respectively. It appears likely from the results obtained that this oil can be separated by distillation into constant boiling fractions which can be separated, in turn, into hydrocarbons of different types by one of the other physical methods available.

The aromatic constituents, extracted from an American asphalt-base spindle oil by liquid sulphur dioxide and subsequently fractionated under reduced pressure, have been studied by Zerbe and Folkens.[217] Examination of the absorption spectra of the fractions showed that those of lower boiling point consisted of substituted derivatives of naphthalene (and possibly benzene) and those of higher boiling

points were derived from phenanthrene and higher polycyclic aromatics. This was also confirmed by the production of the parent aromatic hydrocarbons (benzene and naphthalene) by controlled pyrolysis. The latter operation was effected in a tinned iron tube in the presence of hydrogen, de-alkylation being apparently an important reaction under these conditions.

The oiliness, or friction-reducing, property of natural lubricating oils has been subject of much investigation,[218] but it is still uncertain to what extent this characteristic is dependent upon non-hydrocarbon materials present in the oil. Wardner[219] extracted petrolatum and lubricating oil from Pennsylvania long residuum[220] with acetone and obtained insoluble portions which he termed "proto-petrolatum" or "proto-oil," having highly developed lubricating properties and consisting of unctuous, viscous hydrocarbons of high molecular weight. It was thought by Wardner that these hydrocarbons might be responsible for the accredited "oiliness" of Pennsylvania oils.

A number of workers have attempted to correlate various data on the physical properties of lubricating oils. For example, Keith and Roess[221] prepared a series of curves with which the molecular weight of higher petroleum fractions may be predicted from a knowledge of their viscosities at 100°F. and 210°F. Mair and Willingham[222] noted that the solubility relations of derivatives of monocyclic aromatic hydrocarbons are similar to those of naphthenes with 5 or 6 rings per molecule. With this in mind, Mair and Willingham believe that if such aromatics are present in the lubricant fraction, solvent extraction processes (known or used up to 1936) are discarding these along with the less desirable naphthenes. This topic is, according to these investigators, also of practical importance because such aromatics have viscosity characteristics as good as the best naphthenes besides possessing desirable oxidation qualities.

From their observations, Dunstan and Thole[223] state that the true lubricant is an unsaturated compound; and, they maintain that unsaturation has, in general, the effect of raising viscosity. Their belief is that a lubricating oil should contain a certain proportion of unsaturated hydrocarbons and as large a proportion as is compatible with not too much susceptibility to oxidation, polymerization, gumming and reactivity. Wiggins[224] reviewed the available data on the chemical constitution of hydrocarbons and concluded that the aliphatic hydrocarbons have low viscosities in relation to the number of carbon atoms in the molecule, and that the viscosity-temperature stability increases with chain-length and decreases with branching. Hydrocarbons containing simple cyclic structures have higher viscosities, for a given molecular weight, and also good viscosity-temperature characteristics; whereas, the introduction of polycyclic groups markedly increases the viscosity but reduces the viscosity-temperature stabilities.

A large number of synthetic alkyl derivatives of benzene, naphthalene and biphenyl have been studied from this viewpoint by Mikeska,[225] some of whose conclusions may be briefly summarized as follows. For hydrocarbons of a given molecular weight, the greater the complexity of the ring system, the higher is the viscosity. A long paraffinic side chain increases the viscosity index of a given hydrocarbon to a greater degree than several shorter side chains of the same total number of carbon atoms. Straight side chains are more potent in increasing the viscosity index than are branched chains. The viscosity index of a given aromatic or naphthenic hydrocarbon increases as the ratio of paraffinic to naphthenic or hydroaromatic carbon atoms is increased, provided the number of side chains remains unchanged.

PARAFFIN WAX

This substance is obtained on a large scale by refrigeration of wax-bearing distillates (admixed with a diluent) followed by filtration.[226] The slack wax so obtained is then subjected to a sweating (or partially liquefying) operation, whereby entrained oil is removed. The unmelted residuum is designated crude scale wax. The latter probably consists mainly of paraffin hydrocarbons. For example, a series of paraffins isolated by Sakhanov, Zherdeva and Vasil'ev[227] from Grozny paraffin-base crude oil had melting points varying from 28.3°C. to 71.3°C. and elementary compositions corresponding to $C_{19}H_{40}$ and $C_{35}H_{72}$ respectively. Nametkin and Nifontova[228] examined a German brown-coal paraffin and found it to have an average composition of $C_{26}H_{54}$. They report the specimen contained no more than 10 per cent of isoparaffins possessing the formula $C_{22}H_{46}$.

A white paraffin wax obtained from Pechelbronn by fractionation in a cathode vacuum was found by Yannaquis[229] to crystallize in two distinct modifications: a triclinic form appearing as separate crystals or as a network, and a monoclinic form separating as fibrous needles. From X-ray diffraction observations, Yannaquis concluded that the needle-like variety consists of open-chain paraffins with short branches and the triclinic form is probably composed of saturated cyclic hydrocarbons with long chains.[230] The presence of naphthenic hydrocarbons in refined solid paraffins is confirmed by the work of Müller and Pilat.[231] They determined carbon-hydrogen ratios corresponding to C_nH_{2n+1}, C_nH_{2n}, C_nH_{2n-2} and C_nH_{2n-3} in waxes melting at 76°C., 63°C., 57°C. and 50°C. respectively. A cyclic constitution for the fractions with a smaller hydrogen content was also indicated by the steeper slopes of their temperature-viscosity curves.[232]

[232] A. Berne-Allen, Jr. (Dissertation submitted to the Faculty of Pure Science of Columbia University, 1936) *made an extensive study of the solubility of refined paraffin waxes in petroleum fractions.* J. W. Poole and T. A. Mangelsdorf (*Ind. Eng. Chem.*, 1932, **24**, 1215; *Chem. Abs.*, 1933, **27**, 405; *Brit. Chem. Abs.* **B**, 1933, 7) determined the solubilities of oil and waxes in organic solvents. Specific refraction of commercial waxes in the liquid and solid states has been measured by J. M. Page, Jr. (*Ind. Eng. Chem.*, 1936, **28**, 586; *Chem. Abs.*, 1936, **30**, 6176; *J. Inst. Pet. Tech.*, 1936, **22**, 408A).

Opinions are rather divergent regarding the nature of the crystalline formations in wax, both needles and plates having been observed.[233] It is generally agreed, however, that good crystallization is inhibited by the presence of certain impurities which coat the small crystals and prevent their further growth. According to Fussteig,[234] the so-called amorphous paraffins are small crystals coated with other substances, possibly of an asphaltic nature. Treatment with an alcoholic phenol solution is said to remove the coating and permit formation of needle-shaped crystals, which can then be readily filtered. Sakhanov, Zherdeva and Vasil'ev[235] have shown that addition of even small amounts of ceresins to paraffin wax greatly modifies the crystalline structure as well as its filtering and sweating properties. An X-ray study of recrystallized fractions of paraffins from Fushun shale oil has been made by Sakurada, Fuchino, Tsuneoka and Matsushita[236] who concluded that these materials consisted exclusively of normal paraffins.[237]

The solid hydrocarbons called ceresins display both chemical and physical properties quite different from paraffin wax. In contrast to paraffins, ceresins retain oil very tenaciously and cannot be separated therefrom by the usual process of filtering and pressing. At similar melting points, the ceresins have a much higher molecular weight, specific gravity, viscosity, boiling point and nitrobenzene points than the paraffins. They have a very delicate crystalline structure, the crystals being of needle or short plate shape. Chemically the ceresins are much less stable than solid paraffins and react readily with fuming sulphuric or with chlorosulphonic acid, a fact which has been interpreted to indicate an isoparaffinic structure. On account of their high boiling point, they can be partially separated from paraffin wax. Sakhanov and his collaborators[238] have demonstrated that ceresins can be distilled without decomposition under high vacua but at high pressures they undergo partial transformation to paraffin waxes. A series of ceresins isolated by these investigators from Surakhany crude oils had elementary compositions and molecular weights corresponding to the formulas $C_{37}H_{76}$ to $C_{53}H_{108}$. It was concluded that the latter compounds form a part of the paraffin series and are probably branched chain in structure.

Müller and Pilat[239] report that a specimen of ceresin (from a Boryslaw petroleum) gave fractions having a hydrogen content lower than that required for a paraffin hydrocarbon. Other physical characteristics of these fractions supported a cyclic structure. Another sample, secured during separation of asphalts and resins (from Boryslaw crude oil) with methane at low temperatures followed by repeated precipitation of the ceresin from solvents, appeared to contain both cyclic and paraffinic hydrocarbons. On the other hand, the relatively low refractive indices and specific gravities of the products suggest the presence of large polymethylenic rings, which might be considered as double chains. Also, it has been stated that a wax secured from Midcontinent petroleum contained a portion which melted about 30°C. lower than the corresponding normal paraffins.[239a] This low-melting fraction was said to consist chiefly of cyclic hydrocarbons.

By fractional extraction of "Vaseline" with acetone, André and Bloch[240] effected its separation into three main fractions of decreasing solubility, namely (1) a fraction of low optical activity, having a composition corresponding to $C_{19}H_{38}$ and probably cyclic, (2) a middle fraction with high density and rotation, from which a hydrocarbon, $C_{28}H_{52}$, possibly related to cholestane, was isolated, and (3) the least soluble portion with the composition $C_{30}H_{70}$, probably a mixture of highly condensed cyclic and aliphatic hydrocarbons.

FIG. 6.—Plant for Phenol Extraction of Lubricating Oils.

Wenzel and Weiser[241] examined a Hodonin petroleum and found the presence apparently of a saturated hydrocarbon of the formula $C_{28}H_{46}$. Upon further analysis this hydrocarbon was shown to contain 1 benzene ring and 2 naphthene rings. $C_{15}H_{30}$, a monocyclic naphthene hydrocarbon and $C_{15}H_{28}$, $C_{17}H_{32}$, $C_{18}H_{34}$, $C_{19}H_{36}$ and $C_{20}H_{38}$, all bicyclic naphthenes, were found in the high-boiling fractions of Ni-itsu (Japanese) crude oil.[242] Gruse[243] indicates that $C_{60}H_{122}$ is the largest hydrocarbon isolated from paraffin wax. Low-temperature tar and some of its cracked distillates have been found to contain anthracene, 2-methyl-, 2,6-dimethyl, 2,3,6-trimethyl- and 2,3,6,7-tetramethyl-anthracene.[244]

One application of high-molecular-weight, amorphous, waxy bodies, e.g., petrolatum, is for the spraying of coal or coke to reduce dusting of the latter during handling.[244a] The hydrocarbon material, which is too viscous to flow readily at ordinary temperatures, is heated until it becomes fluid and then applied to the solid fuel in the form of a fine mist. Another procedure comprises dipping coal into an aqueous suspension of paraffin wax.[244b] Asphaltic oils, of 19° to 30° Bé. at 15°C., have also been proposed.[244c]

SOLVENT EXTRACTION

The discovery that certain solvents can be employed to effect a partial segregation of petroleum distillates, particularly lubricating oil fractions, into two fractions of widely different characteristics has resulted in the industrial development of refining processes based on this principle.[245] The main purpose of the solvent treatment of lubricating oils is improvement in viscosity index although an improvement in color, Conradson carbon and resistance to oxidation is simultaneously obtained. The lubricating oil is treated with a solvent or mixture of solvents, usually in a continuous countercurrent system, with the result that undesirable hydrocarbon types (usually referred to as naphthenic oils but probably consisting of cyclic hydrocarbons of several types, including aromatics) are dissolved and the raffinate becomes more paraffinic and exhibits improved viscosity-temperature characteristics. The original oil is thus split up into two main fractions: (1) the insoluble paraffinic portion having enhanced lubricant properties and (2) the soluble portion containing hydrocarbons of inferior properties from the viewpoint of lubrication.

The suitability of any particular solvent for the improvement of lubricating oils depends not only on its selective action but also on its cost, availability, ease of recovery, stability and inertness. Of the many solvents suggested or claimed for this purpose, a number of the following have attained the stage of industrial application.

Nitrobenzene[246] which has a high solvent power so that relatively low temperatures are used.

A mixture of liquid sulphur dioxide and benzene[247] is reported to possess

greater solvent power than sulphur dioxide. Various modifications of solvent extraction with sulphur dioxide alone, or in admixture with other solvents have been suggested.[248]

Phenol has been employed on a technical scale for several years.[249] Suggested modifications include the use of this compound admixed with 5-35 per cent of methanol,[250] a mixture of liquid ethane and propane[251] or diluted with cyclohexanol.[252] According to Kuczynski,[253] phenol cannot be used successfully with

oils containing very high proportions of aromatic hydrocarbons. As a substitute, cresol has been proposed either alone[254] or in conjunction with other solvents.[255] In particular, a mixture of cresol and propane is employed in the "Duo-Sol" process,[256] this combination having specific solvent powers for the unsaturated and cyclic constituents (in cresol) and for the saturated components (in the hydrocarbon). (See Fig. 7.) Since the two solvents are immiscible with each other, an effective separation of the two portions mentioned is said to be accomplished, with a relatively low loss of solvent. The process is reported to be applicable in the preparation of lubricating oils from heavy stocks, both residuals and distillates. A combination of liquefied hydrocarbon gases (ethane or propane) and phenol is suggested for the same purpose.[257]

One advantage of Chlorex (β,β'-dichloroethyl ether) in solvent refining is its high specific gravity which promotes rapid separation of the raffinate and the extract layers.[258] A mixture of this compound with liquid sulphur dioxide with or without liquefied, normally gaseous hydrocarbons, such as propane, is also proposed.[259]

Another solvent-refining agent is furfural.[260] In this instance extraction is usually effected at about 200°F. though a temperature gradient is often employed in countercurrent operations. Aromatic constituents may be removed from naphthas by the use of this liquid.[261]

Crotonaldehyde and acrolein have been recommended for the solvent extraction of lubricating oils.[262] The contact temperature in the case of crotonaldehyde is said to be 60°F.-70°F.

Other organic solvents which have been advanced for the selective removal of hydrocarbons and undesirable non-hydrocarbons from lubricating stocks include

[277] G. H. von Fuchs and A. P. Anderson, paper presented before the Petroleum Division of the A.C.S. in Pittsburgh on Sept. 7-11, 1936.

It has been found that a partial segregation of the constituents of lubricating oils can be accomplished by saturating a solution of such oils in liquefied gases, such as propane, with natural gas under pressure. Early work along these lines is given by Todo.[278] He obtained a product nearly equal to gasoline as a fuel by saturating hydrocarbons obtained by distillation of petroleum with artificial or natural gas under high pressure and at a low temperature. Neyman and Pilat[279] have shown that the thermal effects of dissolving natural gas in hydrocarbons are practically restricted to the heat of compression. Manley[280] has proposed a method of precipitating wax from a hydrocarbon oil chilled to —18°C. by direct vaporization from it of a liquefied normally gaseous diluent, such as propane, in the presence of an inert solid material.

By increasing the pressure of the natural gas (mostly methane) up to 130 atmospheres petroleum residues dissolved in liquid propane can be separated at room temperature into a series of fractions of decreasing density and viscosity.[281]

Table 8 gives some results obtained by Pilat on the fractionation with natural gas of a Rumanian petroleum residue dissolved in liquid propane.

Pilat has determined the pressure at which precipitation is effected with other gases. He used a solution consisting of 1 part of de-asphaltized Venezuelan residue to 6.1 parts of solvent (propane-butane fraction). The pressure of the gaseous precipitant required to effect the first sign of turbidity is indicated in the following table.

Gas	Pressure in atmospheres
CO_2	15
Natural Gas (97.9% methane)	18
Nitrogen	28
H_2	no turbidity up to 86 atmospheres.

fractions which separate out contain propane and small amounts of methane. Pilat remarks that very light heating easily removes the last traces of these solvents.

The use of propane (or other liquefied gases) with oils refined with chloroaniline[282] has been proposed for improving lubricating qualities. In addition to being a useful constituent of a combination of selective solvents for such oils, this hydrocarbon may be employed for the precipitation of asphaltic substances from crude oils and for the dewaxing of residual or distillate oils.[283] (For example, see Fig. 9.)

Liquefied low-boiling hydrocarbons have also been applied as extracting agents in the purification of rosin, with or without the use of an intermediate solvent, as gasoline[284] and in the removal of resins and terpenes from coniferous wood, e.g., long leaf yellow pine.[285]

INORGANIC CONSTITUENTS OF CRUDE OIL

Crude petroleum contains, in addition to water with which it frequently forms stable emulsions, considerable proportions of inorganic materials. Up to 1913, the known inorganic constituents comprised the elements silicon, arsenic, phosphorus, aluminum, iron, calcium, magnesium, copper, silver, gold, vanadium and sodium. This list has subsequently been increased by the addition of the elements titanium, lead, tin, nickel, manganese, chromium, barium, strontium, potassium and lithium. The actual form in which these elements are present is not known; but certain of them, for example, vanadium and iron, may be organically combined. The iron content may be derived from pipe lines and tanks or from ferruginous rocks, and silicates may be found in solution in small quantities owing to their saponaceous properties. In general, the composition of the petroleum ash probably bears a close relation to the class of rock with which the oil has been in contact. Thus, it is suggested that Ohio oils contain lime and magnesia as a result of solvent action on the dolomitic rocks of that region.[286]

The existence of vanadium in the ash of nearly all crude oils is of interest. Vinogradov and Bergman[287] have examined the ash, particularly uranium and vanadium contents, of petroleums and bitumens of the U.S.S.R. They report the latter element (vanadium) is present to the extent of 0.1 per cent in asphaltite[288] and 0.00001 per cent in petroleum and is proportional to the organic content and not to the ash. The theory that vanadium passes into petroleum as vanadium pentasulphide from aqueous solution in the presence of hydrogen sulphide, is considered untenable by these investigators. It is suggested that the vanadium probably came from organic material deposited in sea basins and was concentrated by marine organisms.

According to Longobardi[289] vanadium is present in organic materials including

petroleum, lignites, bituminous shales and natural asphalts, the quantities of this element associated with these substances being too great to be explained by its wide diffusion in nature. Longobardi found that San Rafael petroleum analyzed 0.0377 per cent of ash, of which 11.9 per cent was vanadium pentoxide which corresponds to 0.0045 per cent in the petroleum. A lignite from the same locality contained 53 times more vanadium than the petroleum. The investigations of Fester[280a] indicated that the vanadium content in San Rafael petroleum was more or less proportional to the bituminous content, and independent of other organic material. He suggested that vanadium is present as a result of its precipitation, along with iron and nickel, from aqueous solution by means of hydrogen sulphide produced by bacterial decomposition of the original organic deposits.

FIG. 9.—Plant for Dewaxing with Liquid

The high vanadium content of some petroleum ash, particularly from asphaltic crudes, has been utilized industrially for the recovery of that element. The flue dust from the combustion of Mexican fuel oil in oil-tank ships has been collected and processed in British steelworks.

The ash produced during the combustion of certain oils can be a source of inconvenience owing to the formation of a deposit on the sprayer. This question has been discussed by Seiler,[291] who considers that a proposed ash limit of 0.05 per cent is far too high.

The interesting observation has been made that sulphate-bearing waters suffer reduction to sulphides in contact with paraffin-base oils at temperatures of 30-122°C. even in the absence of bacteria.[292] Analytical methods for the examination of oil field waters have been described by Wood and others.[293]

Chapter 2

Thermal Decomposition of Hydrocarbons

PARAFFIN HYDROCARBONS

The vast amount of fundamental research on various phases of thermal decomposition has resulted in a clearer insight on the complex series of reactions undergone by hydrocarbons when subjected to destructive heat treatment. The practical applications of pyrolysis in the production of various unsaturated and aromatic hydrocarbons are described in subsequent chapters, whereas the object of this chapter is to discuss the topic from the more purely scientific and theoretical viewpoints.

If at first it appears that the numerous investigations have failed in several particulars to illuminate the whole field of pyrolytic reactions, it must be remembered that the subject is a most difficult and complex one, both theoretically and practically. In the cracking of any pure hydrocarbon, the reaction products vary both in kind and amount. The obtaining of any one substance at the expense of the other products depends upon an understanding of the primary and secondary reactions.[1] For some hydrocarbons the primary reactions have been carefully studied, but for any single hydrocarbon the mechanism of the decomposition has not been definitely proved.[2]

According to Travers and Pearce,[3] the results obtained in any process do not represent an ultimate equilibrium; they relate only to a definite but unknown time interval. Other factors being identical, the composition of the product would vary with the time interval, and if any one of these conditions, such as pressure, temperature or concentration is altered, a different set of data results.

Egloff and Wilson[4] have enumerated the difficulties in correlating the data obtained on a single hydrocarbon under different reaction temperatures and contact times. They show that for the same temperature the nature and amounts of the products will vary widely with the contact time, depending on the primary and secondary reactions involved. For the same reaction period, the variation will depend on the energy available at a particular temperature. The significance of these factors may disappear if they are properly adjusted, so that a short contact time and high temperature may give the same products as a longer time and lower temperature. Further accurate data will undoubtedly help to account for the discrepancies encountered and to reconcile certain observations which do not seem to fit into any of the theories so far proposed.[5] The relative stability of the lower paraffins toward pyrolysis has been listed by Egloff and Parrish[6] in the following descending order: methane, ethane, propane, isobutane, butane, neopentane (tetramethylmethane), *n*-pentane, isopentane, *n*-hexane and 2-methylpentane.

---

[1] Primary reaction products are those substances formed in the initial stages of the pyrolysis of hydrocarbons at small percentage decompositions. Secondary reaction products are those which are formed by interaction of primary compounds. For a discussion of primary and secondary cracking reactions see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934, 96.

[4] G. Egloff and E. Wilson, *loc. cit.*

[5] Reviews of pyrolysis have been given by P. K. Frolich and P. J. Wiezevich, *Ind. Eng. Chem.*,

Before discussing the experimental data accumulated on the various types of individual hydrocarbons, it is necessary to describe as briefly as possible the various theories of pyrolysis from a general standpoint. The application of such theories to special cases will be considered afterwards.[7]

THEORY OF FREE RADICALS

The actual existence of free radicals during the thermal treatment of organic compounds has been demonstrated chemically by Paneth and Hofeditz[8] and spectroscopically by Bonhoeffer and Haber[9] and Hogness and Kvalnes.[10] The method of investigation developed by Paneth and his collaborators consists in dissociating gaseous organic materials at low pressures and then passing the gaseous products over metallic mirrors. In this manner, volatile organometallic compounds are formed which can be subsequently identified. In principle, this procedure consists in allowing the free radicals to combine with various metals before the former have time to combine with themselves or with co-existing organic molecules. The experiments have shown that free radicals have an exceedingly short life, their half-period[11] being generally in the magnitude of 10^{-3} second. Rice and his coworkers[12] have applied this procedure to organic compounds, particularly hydrocarbons, heated to 700-1100°C. at low pressures. The radicals identified were methyl ($CH_3—$), ethyl ($C_2H_5—$) and methylene ($CH_2=$). The methyl radical appears to be the chief product of such decompositions. The higher alkyl radicals (except ethyl) could not be detected, probably because of their short life and instantaneous decomposition into unsaturated compounds and smaller free radicals.[13]

The methyl radical reacts with tellurium, selenium, arsenic, antimony, zinc, cadmium, mercury, thallium, lead and bismuth. For identification purposes, the products from tellurium and mercury are of particular value, the former giving dimethyl ditelluride ($CH_3TeTeCH_3$) and the latter dimethyl mercury. Dimethyl

ditelluride is a deep red liquid freezing at −19.5°C. and boiling at 196°C. (with decomposition), comparatively stable in air, insoluble in water but soluble in most organic reagents.[14] Dimethyl mercury will react with alcoholic mercuric bromide to give methyl mercuric bromide, melting at 160°C.[15]

The methylene radical is formed when azomethane is decomposed below 500°C. in a current of diethyl ether or butane. It combines with tellurium, selenium, arsenic and antimony. The product of the action of methylene radical on tellurium is a polymer of telluroformaldehyde, $(CH_2{=}Te)_n$, a red solid of low vapor pressure and insoluble in the usual organic reagents.[16] Evidence gathered by Belchetz and Rideal shows that telluroformaldehyde is readily reduced to dimethyl telluride and dimethyl ditelluride.[17] For this reason the use of iodine was preferred for the detection of methylene radicals, methylene di-iodide being formed even at −65°C. The methylene radical does not combine with zinc, cadmium,[18] mercury, thallium, lead or bismuth.

Active particles consisting of atomic hydrogen, which might conceivably be formed during pyrolysis of hydrocarbons, have been shown not to attack zinc, cadmium or lead mirrors. The possibility of the formation of free radicals of the ethylene type ($-CH_2CH_2-$) has been suggested by Hurd[19] but attempts by Rice and Whaley[20] to isolate them were negative, perhaps due to an exceedingly short life period or to non-interaction with the metallic mirrors used. Experiments to isolate the ethylidene radical ($CH_3CH{=}$) likewise proved unsuccessful.[21]

The Paneth effect may be utilized to determine experimentally activation energies for the dissociation of hydrocarbons into free radicals. If the material under examination is pyrolyzed under low pressure at two or more temperatures, the concentration of free radicals (at the end of the reaction tube) in each case can be measured from the times of disappearance of standard antimony mirrors. If t_1 and t_2 are the observed times at the temperatures T_1 and T_2 (in degrees absolute), the activation energy, E, can be calculated from the formula,

$$\log_e \frac{t_1}{t_2} = \frac{E}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

The above method has been employed by Rice and Johnston[22] in the case of ethane, propane, *n*-butane, *n*-pentane and *n*-heptane, the values of E for these hydrocarbons being 79.5, 71.5, 65.4, 64.0 and 63.2 kg.-cal. per mole, respectively.

It has been shown by Rice and Herzfeld[23] that the monomolecular character of the pyrolysis of ethane and other hydrocarbons is consistent with a chain mechanism involving free radicals.[24] The essential condition is that the chain shall be terminated by a reaction between "two different carriers of the chain."

From observations employing a molecular beam[25] method, Beeck[26] substantiates the free radical theory. Using a platinum or carbon filament covered with a unimolecular layer of water at 1550°C., he found that hydrocarbons (except methane) are completely decomposed in primary reactions, indicating the formation of free radicals by the rupture of carbon bonds. Methane, however, dissociated into the free methylene radical and hydrogen under these conditions. Beeck believes that dehydrogenation of paraffin and olefin hydrocarbons cannot occur unless traces of water or of another non-metallic hydride such as hydrogen sulphide are present, and that this unimolecular layer on the catalytic surface is the true seat of dehydrogenation. Bone[27] contends that in the pyrolysis of the lower hydrocarbons it is necessary to assume the primary formation of free radicals such as methylene, methenyl ($CH\equiv$) and methyl. The evidence is based on spectrographic data obtained in combustion of methane, ethane, ethylene and acetylene.

OTHER THEORIES OF PYROLYSIS

Kassel[28] has proposed a theory based on fundamental valence considerations to account for the production of more than two molecules per molecule of higher paraffin hydrocarbon decomposed. It is assumed that, in the case of *n*-butane for example, two hydrogen atoms at opposite ends of the carbon chain are brought into close proximity and united to yield a hydrogen molecule. The resulting carbon chain is broken in the center to furnish two molecules of ethylene. In the same way, *n*-pentane may yield methane and two ethylene molecules. This theory, which ignores the rôle of free radicals, does not agree with experimental data on the two hydrocarbons cited.

Criegee[29] believes that the thermal rupture of carbon chains occurs by removal of hydrogen atoms in the 1,4 position, the resulting 1,4-di-radical undergoing stabilization by cleavage between atoms 2 and 3. The decomposition of *n*-butane is interpreted in the light of this theory as follows:

$$CH_3CH_2CH_2CH_3 \longrightarrow H_2 + -CH_2CH_2CH_2CH_2- \longrightarrow H_2 + 2CH_2{=}CH_2$$

METHANE

Despite considerable experimental work on the thermal decomposition of methane the exact course of the reaction is still doubtful. Primary dissociation to methylene has previously been shown by Kassel[30] and Storch.[31] Belchetz[32] substantiated these findings by passing methane at 0.1 mm. pressure over a platinum filament heated to 877 to 1027°C. and then over mirrors located 3 mm. from the filament. Since the free radicals combined with iodine mirrors to form methylene iodide and with tellurium to furnish a compound decomposable with bromine to give methylene bromide, Belchetz concluded that the reaction must be

$$CH_4 \longrightarrow CH_2 + H_2$$

The dimerization of methylene radicals on a cooled glass surface yielded ethylene, which further substantiated this proposed mechanism.

In direct opposition to these results, Rice and Dooley[33] observed that only methyl radicals (identified as dimethyl ditelluride) were formed when using a quartz tube at 1200°C. with the tellurium mirror located 1 cm. from the end of the furnace tube. Belchetz's experiments could not be verified, for in the range of temperature (877-1027°C.) no mirror removal was experienced, even when using a larger reaction tube with and without platinum. Rice and Dooley consider that the primary rupture may be represented by:

$$CH_4 \longrightarrow CH_3 + H \quad \text{and} \quad H + CH_4 \longrightarrow H_2 + CH_3$$

These conflicting results have been discussed by Kassel[34] who has shown that the experimental kinetics of the methane decomposition cannot be explained by any mechanism which involves methyl radicals but are perfectly explicable on the assumption that methylene radicals are the primary intermediates. It should be noted that the mechanism of Rice and Dooley involves the production of atomic hydrogen, but these investigators were unable to detect the latter and concluded that the hydrogen atoms initially formed recombine on the walls or react with methane before reaching the mirror. Kassel has pointed out that the non-appearance of hydrogen atoms in the products of pyrolysis is evidence against the mechanism of Rice and Dooley.

Belchetz and Rideal[35] have since demonstrated rather conclusively that methylene radicals are formed in a dynamic or kinetic system at low pressures in contact with carbon and platinum filaments at temperatures of 1100° to 1750°C. The methylene radicals were identified by reaction with iodine to yield methylene diiodide. It was further shown that, owing to the instability and ease of reduction of telluroformaldehyde, the tellurium test for methylene radicals is somewhat unsatisfactory. The gaseous products obtained by passage of methane at high velocity and a pressure of 0.1 mm. over a carbon filament at 1745°C. contained 17 per cent ethane and 2.7 per cent ethylene. The energy of activation for the decomposition of methane on a carbon filament was found to be 95,000 cal.

It is apparent that further work is necessary before the mechanism of the primary dissociation of methane can be properly elucidated but there is no doubt that formation of highly reactive free radicals, either methyl, methylene, or both, represents the initial step and that recombination of these radicals or reaction with methane gives rise to the observed products, namely, ethane, ethylene and acetylene.

It has been stated by Kobozev, Kashtanov and Kobrin[36] that the velocity constants for the formation of ethylene and acetylene from methane (diluted with 40 per cent of nitrogen) in quartz and porcelain tubes at 1160°C. are independent of the reaction chamber materials and are unaffected by the addition of mercury, bichloride of mercury, sodium or sulphur. Although the rate of ethylene formation is considerably reduced by the presence of antimony and sodium chloride, this is attributed to side reactions rather than catalytic poisoning. The rate of carbon formation, however, is 50 to 100 times greater in quartz than in porcelain and is further accelerated by deposition of carbon in the reaction tube. Mercury vapors act as inhibitors for this reaction, but although bichloride of mercury and sulphur are similar to mercury in their action in a porcelain chamber, nevertheless they do effect an increase in the rate of decomposition of methane in quartz vessels. Finkel'shtein and Zabolotzkii[37] noted that a 95 per cent carbonization of methane could be obtained at 1000°C. using a catalyst of fire clay containing 12 per cent nickel monoxide, 2 per cent chromic oxide and 3 per cent copper oxide. This material is not poisoned by hydrogen sulphide and can be used repeatedly if the carbon is removed by superheated steam.

The application of the glow discharge method to the cracking of methane was investigated by Kobozev, Vasil'ev and Gal'braikh.[38] Electrodes of aluminum, copper, zinc, lead or iron brought about a conversion of 1.5 per cent of the methane into ethylenic or acetylenic compounds, but when mercury electrodes were substituted under the same conditions the conversion was 5.2 per cent. By warming the electrodes or employing intermediate mercury electrodes, this can be increased to 14 per cent. The effect is ascribed to an activation of the mercury vapor, from which the energy is transferred to the methane molecule.

Kobayashi and others[39] have studied the range 800° to 1300°C. and found that at 1200°C. a maximum yield of ethylene (4 per cent) is obtained. Above this temperature the production of ethylene is lowered and that of acetylene increases reaching 17.4 per cent at 1300°C. The time of contact when varied between 0.05 and 0.15 second was found to have very little effect. Tropsch and Egloff[40] observed that the time factor is extremely important. At 1400°C. and 50 mm. pressure the production of ethylene falls off from 2.2 to 1.2 per cent when the contact time is increased from 0.0023 to 0.0141 second. Acetylene formation is favored, however, going from 1.6 to 6.0 per cent over the same range of time. Lowering the pressure has a like effect according to Frost[41] who obtained a 95 per cent conversion at 1800°K. (1527°C.) and one atmosphere and again at 1500°K. (1227°C.) and 0.1 atmosphere.

The influence of various contact materials on the production of acetylene at high temperatures has been studied by Klyukvin and Klyukvina.[42] Without catalysts at 1250°C., the yields did not exceed 4.2 per cent of the total methane passed or 11.2 per cent of the total reacting methane. When employing vanadium at 1050°C., the corresponding figures were 3.5 and 48.3 per cent respectively. The best coarse catalyst was kaolin which yielded 1.7 per cent acetylene on the methane passed and 16.9 per cent on the methane consumed at 1050°C. Wulff[43] recommends packing the reaction chamber with silicon carbide (Carborundum) particles. Introduction of methane and air at 1400°C. gave 5 to 6 per cent of acetylene. Fischer and Pichler suggest passing a mixture of methane and oxygen through a

reaction tube heated above 1000° with a contact time of less than 0.01 second.[44] This results in partial combustion with the formation of acetylene and hydrocarbons of a higher carbon content. Thus the optimum yields of acetylene are 6.2 per cent at 1000°C. with 0.0085 second contact time, and 6.6 per cent at 1600°C. with 0.0029 second. Longer periods of heating, however, cause a decreased conversion.

Methane may be converted into liquid hydrocarbons by heat treatment between 400° and 1100°C. in the presence of mercury or cadmium vapors.[45] A yield of 12 g. of tar and 12 ml. of oil per cubic meter of methane was obtained by Oda[46] who used quartz tubes of 3 to 15.5 mm. internal diameter and catalysts of silica and pumice stone with and without ferric oxide and nickel. By diluting the methane with hydrogen the yield of oil and tar was lowered, even when larger reaction tubes, higher temperatures and longer heating periods were employed. Dilution of the feed gas with oxygen resulted in partial combustion with a negligible formation of tar and oil.

ETHANE

The main reaction in the early stages of decomposition of ethane is one of dehydrogenation to ethylene, which occurs without catalysts at about 650°. Rice has suggested a mechanism involving the decomposition to two methyl radicals[47] which then initiate chain reactions. Sachsse[48] determined the concentration of hydrogen atoms produced during the thermal decomposition of ethane at 560 to 590°C. to be twice as great as corresponds with the equilibrium value for the dissociation of pure hydrogen. This shows that part of the ethane decomposes primarily into methyl radicals which form hydrogen atoms by chain reactions. However, it was also pointed out that the concentration of hydrogen atoms is only about 0.001 of the value calculated according to the Rice theory, which holds that all the ethane decomposes by chain reactions initiated by the formation of methyl radicals. Sachsse concluded, therefore, that only a small part of the ethane decomposes primarily into radicals.

Belchetz and Rideal,[49] in studying the decomposition of ethane at low pressures in contact with carbon filaments at 1450 to 1800°C., have failed to obtain any evidence of the formation of methyl or ethylidene radicals. The very close agreement between the activation energy of 94.6 kg.-cal. for this reaction and that obtained for methane (95 kg.-cal.) using the same method, suggests the possibility that the same process is involved, that of the removal of two hydrogen atoms as a molecule from the same carbon atom as first suggested by Kassel.[50] If this is the mechanism, the ethylidene radical must undergo tautomeric conversion to ethylene immediately after formation. However, Belchetz and Rideal consider it much more likely that ethylene is the primary product.

The decomposition of a molecular beam of ethane projected on to a hot plati-

that some liquid products were formed by polymerization of butadiene and acetylene resulting from dehydrogenation of ethylene.

start

PROPANE

Propane pyrolyzes according to the following schemes at atmospheric pressure:

$$(1)\ C_3H_8 \rightleftharpoons C_3H_6 + H_2$$
$$(2)\ C_3H_8 \longrightarrow C_2H_4 + CH_4$$
$$\text{and}\ (3)\ 2C_3H_8 \longrightarrow C_3H_6 + C_2H_6 + CH_4$$

According to Tropsch, Thomas and Egloff,[55] reaction (1) is a true equilibrium and should be suppressed by the application of pressure, whereas (2) should not be influenced.[56] Reaction (3) plays only a small role until the pressure is raised.

---

[55] H. Tropsch, C. L. Thomas and G. Egloff, *Ind. Eng. Chem.*, 1936, 28, 324; *Brit. Chem. Abs.* B, 1936, 535; *J. Inst. Pet. Tech.*, 1936, 22, 203A; *Chem. Abs.*, 1936, 30, 3212.

[56] In the first instance, the reversed reaction involves the union of hydrogen and propene to give

Then it should predominate more and more, since it is bimolecular and its rate is proportional to the concentration of the substance undergoing change. This reaction is thermodynamically possible and also probable, as the calculations of Lang and Morgan[57] on the free energy change give —11,830 cal. at 627°C.

Using a carbon filament at 1650°C., Belchetz and Rideal[57a] were able to identify only propene in the decomposition products. At 1750°C., ethylene was also found. The energy of activation of propane on carbon was calculated to be 94.2 kg.-cal., which is very close to that obtained for methane and ethane by this method.

Dintzes and Frost[57b] have pointed out that the pyrolysis of propane at 616-666°C. in a quartz tube at low pressure does not follow a unimolecular course but probably involves a chain mechanism. Paul and Marek[58] found that dissociation in copper and fused silica tubes is not affected by changes of reactor surface-volume ratio. In the temperature range 550° to 650°C. at atmospheric pressure the relation between the equilibrium constant and the temperature is governed by the equation,

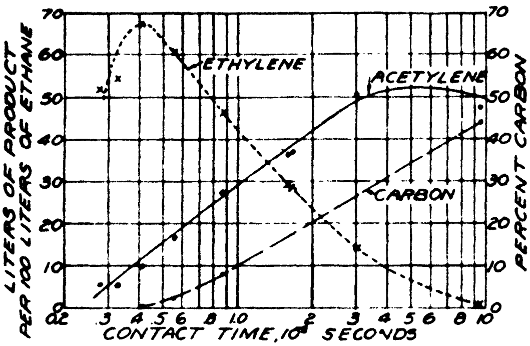

FIG. 11. Pyrolysis of Ethane at 1400° C. and 50 mm. Pressure. (H. Tropsch and G. Egloff)

Courtesy Industrial and Engineering Chemistry

$$\log_{10}k = 16.60 - \frac{74850}{2.3RT}$$

The results of Tropsch, Thomas and Egloff[59] indicate that the bimolecular reaction (3) may account for as much as 70 per cent of the propane decomposed at 555-585°C. under a pressure of 725 lb. per sq. in. At 555°C. with a contact time of 95 seconds, the proportions of propane decomposed (about 12 per cent of the total feed) according to reactions (1), (2) and (3) were 6.8, 33.0 and 54.0 per cent, respectively. At 585°C. with 87 seconds contact 0.9 gal. of liquid hydrocarbons per 1000 cu. ft. of gas was obtained and about 30 per cent of the propane was consumed per passage.

The pyrolysis of propane at 600, 650 and 700°C. and under 1 and 7 kg. per sq. cm. pressure has been investigated by Egloff, Thomas and Linn.[60] At the lower

---

propane (a hydrogenation process), whereas the second reaction would require a direct union between ethylene and methane molecules, which is not a reversible process, and hence the effect of pressure.

pressure, the highest concentration of propene (14 per cent) was attained at 700°C. and 5.4 seconds contact time, with 35 per cent of the propane undergoing decomposition. Optimum conditions for the formation of ethylene at 1 kg. per sq. cm. pressure were at 700°C. and a contact time of 19 seconds, corresponding to a 23.9 per cent content in the exit gas. The application of pressure lowers the proportion of olefins and yields somewhat, but at the same time greatly increases the production rate. The investigators point out that the effect of increasing the reaction time increases the extent of the reaction and also the concentration of unsaturates up to a maximum, after which longer durations caused only a decrease in the latter. It was also noted that the propene maxima point always occurred at shorter contact times than that of ethylene.

In the thermal treatment of propane at 650-860°C. under atmospheric pressure in a steel alloy (Sicromal) tube, it was noted by Schmieden[61] that the highest yields of unsaturates occurred in the range 730-790°C. Thus, at 760°C. with a contact time of 2 seconds a 72 volume per cent yield resulted, one-third of which was propene and higher olefins. Carbon deposition amounted to about 1 per cent (by weight) of the original propane.

FIG. 12.—Pyrolysis of Propane at 1100°C. and 50 mm. Pressure. (H. Tropsch and G. Egloff)

A 75-80 per cent yield of unsaturated hydrocarbons (ethylene and propene) was obtained by Frolich and Wiezevich[62] from propane diluted with 70 per cent air and heated to 675°C. for 30 seconds in a copper reactor. Low yields of liquid products resulted with simultaneous cracking and polymerization at 1 atmosphere, and with pyrolysis at 840°C. and 1 atmosphere followed by polymerization at 650°C. and 48 atmospheres pressure. The optimum conversion (7.75 gal. per 1000 cu. ft.) was obtained after cracking by dehydrogenation in the presence of copper oxide and subsequent polymerization at 400°C. and 170 atmospheres.

According to Lang and Morgan,[63] varying the partial pressure of propane by dilution with steam clearly shows the importance of the bimolecular reaction. Experiments were carried out in the range of 600-700°C. at constant rate of contact. Up to pressures of 0.2 atmosphere, methane, ethylene, propene and hydrogen are produced in approximately equal amounts. Above this pressure the production of ethane becomes appreciable and that of ethylene and hydrogen tends to decrease.

The work of Cambron and Bayley[64] indicates the necessity of employing conditions of turbulent flow of gases in hot tubes for optimum formation of intermediate products. High conversions to aromatic hydrocarbons can be obtained by subjecting gaseous propane to turbulent flow through alloy steel tubes (containing 18 per cent of nickel) at temperatures as low as 800°C. under slight positive pressure. Yields of 23.3 lb. of light oil per 1000 cu. ft. of propane passed were obtained at 800°C., together with 10 lb. of liquid boiling above 200°C. The light oil contained 64 per cent benzene, 14 per cent toluene, 7.8 per cent styrene and small proportions of cyclopentadiene, xylenes and higher aromatics. The higher-boiling liquid con-

[64] A. Cambron and C. H. Bayley, *Can. J. Research*, 1933, 9, 583, 591; 1934, 10, 145; *Brit. Chem. Abs.* B, 1934, 308; *Brit. Chem. Abs.* A, 1934, 507; *Chem. Abs.*, 1934, 28, 1506; *J. Inst. Pet. Tech.*, 1934, 20, 74A.

sisted of 25 per cent naphthalene, 12.5 per cent anthracene, and smaller percentages of mono- and dimethyl-naphthalenes, acenaphthene and phenanthrene. The gaseous products resulting were ethylene (which represented 30 per cent of the propane decomposed, butadiene (about 5 per cent) and small amounts of acetylene.

High-temperature-low-pressure pyrolysis yields large quantities of ethylene and acetylene, as can be seen from the results of Tropsch and Egloff.[65] Table 12.

The striking similarity between the pyrolysis of propane and that of ethane can best be noticed by comparing Figs. 10 and 12 for treatment at 1100°C. and Figs. 11 and 13 for pyrolysis at 1400°C. The maximum yields of ethylene are approximately the same in all four cases, but the contact times are much shorter at the higher temperature. Carbonization is slightly more pronounced in ethane than in propane at 1400°C.

N-BUTANE

In the initial stages of the thermal decomposition of *n*-butane the principal reactions are:

$$\begin{array}{lll}(1)\ n\text{-}C_4H_{10} & \rightleftharpoons & n\text{-}C_4H_8 + H_2 \\ (2)\ n\text{-}C_4H_{10} & \longrightarrow & C_3H_6 + CH_4 \\ (3)\ n\text{-}C_4H_{10} & \longrightarrow & C_2H_4 + C_2H_6\end{array}$$

Reaction (1), accounting for 16 per cent of the products at normal pressure, is a true equilibrium and may be suppressed by increasing the pressure.[66] The others are non-reversible and would not respond to pressure changes. Reaction (2) accounts for 48.5 per cent and (3) for 34.5 per cent of the products at 600°C. and atmospheric pressure.

In addition, two bimolecular reactions have been proposed by Tropsch, Thomas and Egloff. They are:

$$\begin{array}{llll} & (4)\ 2n\text{-}C_4H_{10} & \longrightarrow & n\text{-}C_4H_8 + C_3H_6 + CH_4 \\ \text{and} & (5)\ 2n\text{-}C_4H_{10} & \longrightarrow & n\text{-}C_4H_8 + 2C_2H_6\end{array}$$

The true significance of these latter equations will be discussed subsequently.

The similarity in the primary decomposition of the lower paraffins has been shown by Belchetz and Rideal[67] using a carbon filament heated to 1400° to 2000°C. The energies of activation calculated from the data obtained were: methane, 95, ethane, 94.6, propane, 94.2 and butane, 93.2 kg.-cal. per mole. It was concluded that because of the closeness of these values the primary dissociation must be of the same general type, i.e., the production of molecular hydrogen and the complementary olefin. The latter may decompose to methylene and the next lower olefin. Methylene subsequently undergoes reaction with the surrounding molecules.[68]

The data of Paul and Marek[69] for the limited decomposition of *n*-butane in copper and fused silica tubes show that the reaction at atmospheric pressure is homogeneous and unimolecular, the velocity constants in the temperature range 530-625°C. being represented by the equation:

$$\log_{10}k = 17.05 - \frac{73900}{2.3RT}$$

[67] L. Belchetz and E. K. Rideal, *J.A.C.S.*, 1935, **57**, 1168, 2466; *Brit. Chem. Abs.* **A**, 1936, 169; *J. Inst. Pet. Tech.*, 1936, **22**, 86A; *Chem. Abs.*, 1935, **29**, 6128; 1936, **30**, 1641.

[68] According to L. S. Echols, Jr., and R. N. Pease, (*J.A.C.S.*, 1936, **58**, 1317; *Brit. Chem. Abs* **A**, 1936, 1090; *Chem. Abs.*, 1936, **30**, 5933.), the cracking of propane, n-butane and isobutane at 425°C. is induced by the presence of ethylene oxide. Ethane, however, they report to be unaffected under these conditions.

[69] R. F. Paul and L. F. Marek, *Ind. Eng. Chem.*, 1934, **26**, 454; *Brit. Chem. Abs.* **A**, 1934, 603; *Chem. Abs.*, 1934, **28**, 3973.

Variation of reaction surface-volume ratio, dilution with nitrogen and change of surface from copper to silica were found to have no effect on the reaction velocity.

Hurd, Parrish and Pilgrim[70] have pyrolyzed *n*-butane at low temperatures in empty Pyrex tubes. The primary products at incipient decomposition temperatures included methane, ethane, ethylene, propene and traces of hydrogen. At 365°C., 0.46 per cent dissociation was noted; this was increased to 5 per cent at 415°C. No evidence could be found to support the statement of Norris and Thomson[71] that there is a scission at any specific C-C bond location in the molecule if temperatures near the initial decomposition values are used.

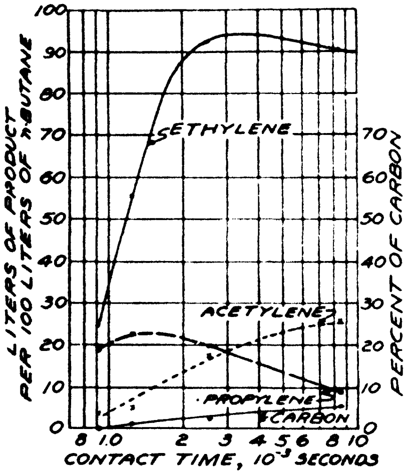

FIG. 14.
Pyrolysis of *n*-Butane at 1100°C. and 50 mm. Pressure. (H. Tropsch and G. Egloff)

Courtesy Industrial and Engineering Chemistry

Over the range 525° to 555°C. at 725 lbs. per sq. in. pressure, Tropsch, Thomas and Egloff[72] found that butane was decomposed in the following manner: 1.4 per cent dehydrogenation to butene according to reaction (1), 33.6 per cent demethylation to propene (2), 30.0 per cent to ethylene and ethane (3), 31.9 per cent to butene, propene and methane (bimolecular) (4), and 3.2 per cent to butene and ethane (bimolecular) (5). The importance of pressure can be seen in that reaction (1), a true equilibrium, was greatly suppressed, the normal value at ordinary pressure in approximately the same temperature range being 16 per cent, whereas the bimolecular reaction (4) which under ordinary conditions is usually negligible, becomes very nearly the predominating one. The following equation for evaluation of contact time was proposed:

$$C = V_r \times 60t \times \frac{273}{T} \times P \times \frac{2}{V' + V^\circ}$$

where C = contact time, in minutes
V_r = volume in cc. of apparatus at reaction temperature
t = total time of experiment, minutes
P = operating pressure, atmospheres
V' = volume in cc. under standard conditions of gas charged to apparatus in time t
V° = volume in cc. under standard conditions of gas and vapor recovered from apparatus in time t
T = absolute temperature

[70] C. D. Hurd, C. I. Parrish and F. D. Pilgrim, *J.A.C.S.*, 1933, 55, 5016; *J. Inst. Pet. Tech.*, 1934, 20, 162A; *Brit. Chem. Abs.* A, 1934, 167; *Chem. Abs.*, 1934, 28, 737.

[71] J. F. Norris and G. Thomson, *J.A.C.S.*, 1931, 53, 3108; *Chem. Abs.*, 1931, 25, 4842; *Brit. Chem. Abs.* A, 1931, 1147.

[72] H. Tropsch, C. L. Thomas and G. Egloff, *loc. cit.*

This formula was developed assuming that the ideal gas laws hold under these conditions. With the gases ordinarily used, this is nearly true. The greatest error (about 5 per cent) was with *n*-butane at 550°C. and 1000 lbs. per sq. in.

It has been shown by Hurd and Pilgrim[73] that the decomposition of *n*-butane at 600°C. pursues the same course at roughly the same reaction velocity in iron, nickel and quartz tubes. Monel metal, on the other hand, violently catalyzes the decomposition of butanes at 600°C., resulting mainly in complete dissociation to carbon and hydrogen. At 500°C., however, it exerts very little action. Hurd and Pilgrim obtained their time of contact from the formula:

$$t = VT_1/FT_2$$

where t = contact time in minutes, V = volume of the tube in cc., T_1 = absolute temperature of entering gas, T_2 = absolute temperature of heated gas, F = average rate of flow of gas through the tube, cc. per minute. This equation, also based on the ideal gas laws, can be used only at atmospheric pressure. It shows, however, that if the rate of flow and the temperature of the incoming gas are maintained constant, the product of the contact time and reaction temperature will equal a constant value. This explains the fact that the products obtained from *n*-butane at about 400°C. are very similar to those formed at 600° and 700°C. using correspondingly shorter periods of contact.[74]

The pyrolysis of *n*-butane in non-catalytic metal tubes at 600° and 650°C. and at 1 and 7 kg. per sq. cm. pressure has been discussed by Egloff, Thomas and Linn.[75] The concentration of *n*-butene in the exit gas reached a maximum 5 per cent at 750°C., 7 kg. per sq. cm. and a time of contact of about 5 seconds. Propene formation was highest under the same conditions of temperature and pressure, but with heating periods of 18 seconds, amounting to 17.5 per cent by volume of the reaction mixture. On the other hand, the optimum concentration of ethylene was attained at 660°, 1 kg. per sq. cm. and 142 seconds. In these tests, the rates of formation of the olefins at 7 kg. are from 8 to 10 times those at atmospheric pressure. High temperature-low pressure pyrolysis at short contact times distinctly favors the production of ethylene. As mentioned previously, the importance of the duration of the reaction period is stressed by Tropsch and Egloff.[76] Their data, corresponding to 1100°C. and 50 mm. pressure, are given in Table 13.

[76] H. Tropsch and G. Egloff, *Ind. Eng. Chem.*, 1935, **27**, 1063; *Brit. Chem. Abs.* **B**, 1935, 1035; *Chem. Abs.*, 1935, **29**, 7935; *J. Inst. Pet. Tech.*, 1935, **21**, 408A.

Tropsch and Egloff believe the cracking into ethane and ethylene to be the primary reaction, and dehydrogenation to ethylene a secondary one, although with short contact times it seems to them more probable that the decomposition is to 2 molecules of ethylene and 1 of hydrogen, in accordance with the views of Criegee.[77]

The relations between the yield of products and contact time are shown in Fig. 14. Ethylene formation is the greatest with this hydrocarbon, being about 33 per cent more than in the case of ethane or propane. Under similar conditions, acetylene and propene are produced in greater amounts than when using propane but carbonization proceeds to about the same extent.

[77] R. Criegee, *Ber.*, 1935, **68**, 665; *Brit. Chem. Abs.* **A**, 1935, 727; *Chem. Abs.*, 1935, **29**, 3975. His views have been discussed in the introduction to this chapter.

ISOBUTANE

The two main primary reactions occurring in the thermal decomposition of isobutane may be represented by the equations:

$$(1)\ iso\text{-}C_4H_{10} \longrightarrow iso\text{-}C_4H_8 + H_2$$
$$\text{and}\ (2)\ iso\text{-}C_4H_{10} \longrightarrow C_3H_6 + CH_4$$

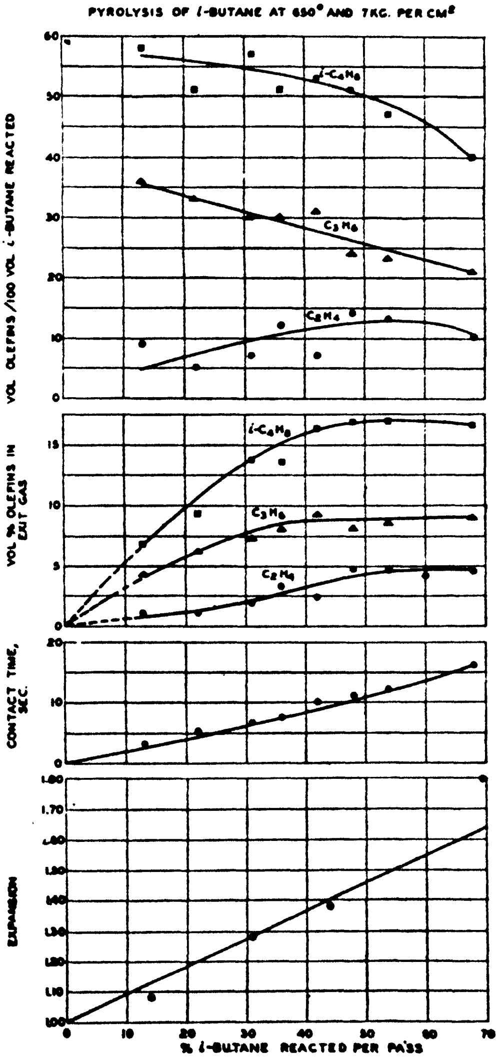

FIG. 16.
Pyrolysis of Isobutane at 650° C. and 7 kg. per sq. cm. (G. Egloff, C. L. Thomas and C. B. Linn)

Courtesy Industrial and Engineering Chemistry

In addition, according to Tropsch, Thomas and Egloff,[78] there is also a bimolecular reaction,

$$(3)\ 2\ iso\text{-}C_4H_{10} \longrightarrow iso\text{-}C_4H_8 + C_3H_8 + CH_4$$

---

[78] H. Tropsch, C. L. Thomas and G. Egloff, *Ind. Eng. Chem.*, 1936, **28**, 324; *Brit. Chem. Abs.* B, 1936, 535; *J. Inst. Pet. Tech.*, 1936, **22**, 203A; *Chem. Abs.*, 1936, **30**, 3212.

which becomes very prominent at high pressures. At 555°C. and 725 lbs. per sq. in. pressure, only 5.9 per cent decomposes according to equation (1), whereas reactions (2) and (3) represent 37.8 and 39.9 per cent of the dissociation. Small amounts of ethylene and ethane were also formed.

The velocity of dissociation at 550° to 610°C. under atmospheric pressure has been investigated by Paul and Marek.[79] As in the case of *n*-butane, the reaction is homogeneous and unimolecular, and is unaffected by change of surface or by dilution with nitrogen. Under conditions of limited decomposition, the velocity constant and temperature are related by the equation:

$$\log_{10} k = 14.89 - \frac{66{,}040}{2.3RT}$$

The results of Egloff, Thomas and Linn[80] on the dissociation of isobutane at 650°C. and pressures of 1 and 7 kg. per sq. cm. are represented graphically in Figs. 15 and 16, respectively. From the latter figure, it will be seen that the maximum concentration of isobutene in the exit gas was 17 per cent, corresponding to a yield of 45 per cent with a 12 second heating time. On the other hand, at 1 kg. per sq. cm. pressure, the optimum content is about 21 per cent at 21 seconds. The proportion of propene reaches its greatest value (12 per cent) at the lower pressure with a contact period of 39 seconds.

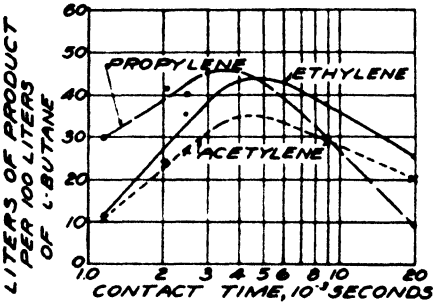

FIG. 17.
Pyrolysis of Isobutane at 1100°C. and 50 mm. Pressure. (H. Tropsch and G. Egloff)

Courtesy Industrial and Engineering Chemistry

High-temperature pyrolysis of isobutane takes a different path from that of the normal gaseous paraffins under the same conditions, propene and acetylene being formed in higher yields in this case. Tropsch and Egloff[81] have investigated the decomposition at 1100°C. and 50 mm. pressure. Their data are given in Table 14.

It is interesting to note that equation (1) is entirely suppressed at contact times of more than 0.00203 second. The formation of ethylene is quite prominent, as will be seen from Fig. 17 showing the relation between yield and time of contact. From the graph, the maximum yields per 100 liters of isobutane charged with the corresponding contact times are: propene, 46 l. at 0.0035 second, ethylene, 44 l. at 0.0048 second, and acetylene, 35 l. at 0.0045 second.

PENTANES

The primary products obtained in the pyrolysis of the three isomeric pentanes are quite varied. Frey and Hepp[82] have studied the decomposition of these hydrocarbons at relatively low temperatures and pressures under conditions of limited dissociation. Their results are in direct conflict with the conclusions of Norris and Thomson[83] that at low temperatures rupture of the carbon chain can be made to take place at preferred points. Frey and Hepp have established the fact that the carbon-carbon bonds in all points in the molecule exhibit similar tendencies to break both in branched as well as normal chains. Under conditions of limited pyrolysis in cases where olefins capable of existence in several isomeric forms may be produced, the double bond remains the point of rupture. Naturally, isomerization of such olefins may occur under more exacting pyrolytic conditions, but the normal paraffins yielded only olefins under the comparatively mild conditions used by these investigators. Where olefins were produced by the scission of a side chain from isopentane and neopentane, the double bond at the point of rupture was located in the inner and not the terminal position.

FIG. 18.—Effect of Dilution on Decomposition of Pentane at 600°C. (J. J. Morgan and J. C. Munday)

n-Pentane. On the basis of the Rice mechanism,[84] the decomposition of n-pentane may be summed up as:

$$n\text{-}C_5H_{12} \longrightarrow 2C_2H_4 + CH_4$$
$$n\text{-}C_5H_{12} \longrightarrow C_3H_6 + C_2H_6 \text{ (or } C_2H_4 + H_2)$$
$$n\text{-}C_5H_{12} \longrightarrow C_4H_8 + CH_4$$

[84] F. O. Rice, *J.A.C.S.*, 1931, **53**, 1959; *Chem. Abs.*, 1931, **25**, 2967; *Brit. Chem. Abs.* A, 1931, 819. See also F. O. and K. K. Rice, "The Aliphatic Free Radicals," The Johns Hopkins Press, Baltimore, 1935.

In agreement with these predictions, Frey and Hepp[85] find that the primary products at limited dissociation in the range of 396° to 560°C. are hydrogen, methane, ethylene, ethane, propene, 1-butene and pentenes, with only small amounts of other products.

Morgan and Munday[86] investigated the decomposition of pentane at 600-800°C. Dilution of the hydrocarbon with steam shows that the rate of dissociation is independent of the concentration, which indicates that the primary decomposition is essentially of the first order. See Table 15. The results are in accord with the Rice mechanism but do not agree with that proposed by Kassel.[87] The formation of propane is explained by the equation:

$$C_5H_{12} \longrightarrow C_3H_8 + C_2H_4$$

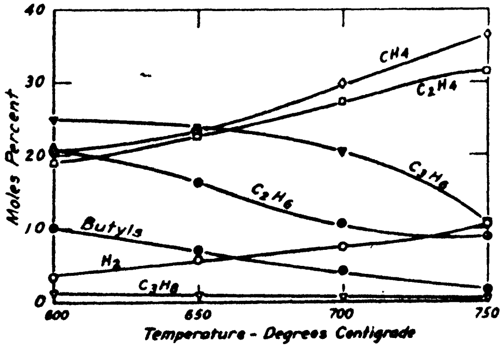

FIG. 19.
Thermal Decomposition of Pentane at Atmospheric Pressure. (J. J. Morgan and J. C. Munday)

Courtesy Industrial and Engineering Chemistry

Fig. 18 shows the effect of pressure on pyrolysis of pentane at 600°C. Increased dilution increases the formation of ethylene and hydrogen at the expense of the ethane, which is perfectly explicable in terms of the Rice theory. The effect of increased temperature can be readily ascertained from Fig. 19.

Isopentane. Isopentane which contains primary, secondary and tertiary carbon atoms may be expected to undergo decomposition with rupture of the carbon chain at all of the available positions. Thus, in accordance with the Rice mechanism, demethylation to 2-butene and isobutene, de-ethylation to propene, de-ethylenation to propane and dehydrogenation to pentenes may be expected.[88] Products obtained at 398-575°C. by Frey and Hepp[89] substantiate these reactions.

Neopentane (tetramethylmethane). According to Rice[90] the only chain reaction possible in the decomposition of this hydrocarbon should be one involving the formation of methane and isobutene. Again, Frey and Hepp[91] substantiate the Rice mechanism, at 575°C. the products being methane and isobutene together with traces of hydrogen and 1-butene.[92]

The data of Frey and Hepp on the three pentanes are listed in Table 16.

n-HEXANE

The pyrolysis of *n*-hexane at normal pressure and at temperatures slightly above incipient decomposition (520°C.) has been carried out by Dintzes and Frost.[93] The results indicate four primary decomposition equations:

$$
\begin{aligned}
&(1)\quad n\text{-}C_6H_{14} \longrightarrow C_6H_{12} + H_2\\
&(2)\quad n\text{-}C_6H_{14} \longrightarrow C_5H_{10} + CH_4\\
&(3)\quad n\text{-}C_6H_{14} \longrightarrow C_4H_8 + C_2H_6\\
&(4)\quad n\text{-}C_6H_{14} \longrightarrow C_3H_6 + C_3H_8
\end{aligned}
$$

which are always accompanied by secondary reactions,

$$
\begin{aligned}
&(5)\quad C_6H_{12} \longrightarrow C_4H_8 + C_2H_4\\
&(6)\quad C_6H_{12} \longrightarrow 2C_3H_6\\
&(7)\quad C_5H_{10} \longrightarrow C_3H_6 + C_2H_4\\
&(8)\quad C_4H_8 \longrightarrow 2C_2H_4
\end{aligned}
$$

The latter equations are greatly affected by the temperature and the time of contact.

U.R.S.S.*, 1933, 4, 153; *Brit. Chem. Abs.* A, 1934, 259; *Chem. Abs.*, 1934, 28, 2169. *Foreign Petroleum Tech.*, 1934, 2 (3), 81; *J. Inst. Pet. Tech.*, 1934, 20, 404A.

In these experiments, the hydrocarbon was heated almost to the cracking temperature and then passed through copper-lined iron tubes immersed in a metal bath. At 525° to 565°C. and a contact time of 6.1 to 90.8 seconds, a 3 to 8 per cent dissociation was obtained. Hexane decomposes mainly according to reactions (2) and (3) and only slightly following (1) and (4). Secondary decompositions proceed to the extent of 40 to 60 per cent. Over this temperature range the energy of primary decomposition is given as 64.5±1.5 kg.-cal. per mole and the velocity constant as

$$\log_{10}k = 14.22 - \frac{14{,}105}{T} \pm 0.031$$

These investigations were furthered by Dintzes and Zherko[94] to include more profound decomposition. At 588°C. with a contact time of 20 to 200 seconds, 27 to 60 per cent dissociation was observed. From the decomposition velocity constants calculated according to both first- and second-order equations, it was demonstrated that the cracking relations of this hydrocarbon and also of octane under the same conditions cannot be described by the classical equations of chemical kinetics. For a first-order process, the velocity constant falls off sharply with increase in per cent of decomposition from 10 to 60. This may be attributed to the retarding action of some of the reaction products. The equation,

$$kt = \left[\ln \frac{1}{1-x}\right] - \beta x$$

is adapted to the decomposition.

The theory that the retardation is caused by inactivation of free radicals formed early in the decomposition by their recombination is not accepted by Dintzes and Zherko. Their conclusion is that the free radicals react with the products already formed to yield a complex which is not broken up in collision with a new molecule. The original hydrocarbon is decomposed unimolecularly by heat into radicals by rupture of the carbon bonds. These radicals in turn are transformed into olefins and simpler radicals, such as methyl and ethyl, which react with molecules of the original hydrocarbons, detaching hydrogen atoms and forming the corresponding complex radicals which decompose anew into olefins and simpler radicals. The interaction of the radicals with the original hydrocarbon accounts for the rapid increase in reaction velocity at the start of the decomposition, which period is of relatively short duration. At the same time the radicals begin to become inactivated by the interaction with other products. The result of these two simultaneous processes is that the reaction velocity passes through a maximum and then gradually diminishes.

As a result of their studies on *n*-hexane and *n*-octane, Moldavskii, Kobuil'skaya and Livshitz[95] concluded that thermal isomerization of hydrocarbons is brought about chiefly as the result of secondary decompositions of the reaction products and not by rearrangement of the hydrocarbon skeleton. This was based on the observation that heat treatment at atmospheric pressure and temperatures up to about 600°C. produced practically no isomerization or change of the hydrocarbons. However, the factors that increased the degree of cracking (i.e., time, temperature and catalytic action of iron chamber walls) also increased the isomerization.

Griffith[96] found that the decomposition of hexane at 500°C. is greatly influenced by the addition of silica to a molybdenum oxide catalyst. The maximum effect is reached at a concentration of 4 moles of promoter to 100 of catalyst. The same ratio holds when the oxides of sodium, chromium, cerium, aluminum, boron, barium and thallium are used as promoters, but it is one-half as high with easily reducible oxides such as those of lead, iron or copper.

Pearce and Newsome[97] have studied the effect of pressures of about 1000 atmospheres at temperatures between 430° and 520°C. at heating times varying from a few minutes to 2 hours. In the interval 460-490°C., the production of gaseous paraffins predominates, methane, ethane, propane and butane being formed in percentages of 25, 47, 15 and 7, respectively. The amount of gaseous olefins produced is very small and tends to diminish with rise in temperature. At 497°C. an abundant carbonization begins and the proportion of methane is noticeably increased and continues to do so with higher temperatures. Liquid hydrocarbons, including cycloparaffins, benzene, substituted benzenes and higher olefins are also obtained.

At 670° to 750°C., under atmospheric pressure, decomposition is essentially in accordance with the equation,[98]

$$C_6H_{14} \longrightarrow CH_4 + C_2H_4 + C_3H_6$$

The formation of tar and coke, which are produced in small amounts, was inhibited by the dilution of the hydrocarbon with steam.

HIGHER PARAFFIN HYDROCARBONS

Experimental data on the pyrolysis of higher paraffin hydrocarbons are apparently not available. The primary decomposition of these hydrocarbons is best represented by a series of equations indicating the rupture of the carbon chain at any position with the formation of an olefin and the complementary lower paraffin, or, at the limit, hydrogen. This rule, though not entirely self-sufficient, satisfactorily represents the chief mode of decomposition. A more complete picture is furnished by the theory of free radicals. On the assumption that methyl, ethyl, isopropyl and *ter*-butyl radicals are stable and that the relative chances of loss of primary, secondary and tertiary hydrogen atoms can be expressed quantitatively by the ratio 1:2:10 at 600°C., Rice[99] has calculated the proportions of various hydrocarbons to be expected in the primary decomposition of certain higher paraffins. The results of this calculation are shown in Table 17.

Heptane. Matignon and Seon[100] find that the pyrolysis of heptane at 700°C. in a quartz tube at atmospheric pressure furnishes large quantities of higher olefins but only small amounts of ethylene. Dilution of the hydrocarbon with steam increases the formation of ethylene at the expense of the higher homologues. At 935°C. with about 80 per cent dilution, the yield of ethylene is 76 per cent.[101]

It is interesting to note that *n*-heptane is isomerized to the extent of 20-25 per

[101] F. O. Rice and O. L. Polly (*Ind. Eng. Chem.*, 1935, **27**, 915; *Brit. Chem. Abs.* **A**, 1935, 1229; *Chem. Abs.*, 1935, **29**, 6578) obtained cyclohexane, *n*-heptane and tetradecane in the pyrolysis of di-*n*-heptyl mercury. The formation of the cyclohexane is attributed to the direct decomposition of the free heptyl radical, and not to polymerization of ethylene. F. O. Rice (British P. 407,036, 1934; *Chem. Abs.*, 1934, **28**, 4847; *Brit. Chem. Abs.* **B**, 1934, 444; *J. Inst. Pet. Tech.*, 1934, **20**, 332A) has suggested a method of preparing organo-lead compounds, namely by heating the hydrocarbons to 800-1000°C. at reduced pressure in the absence of air and passing the vapors over finely divided lead. The reaction mixture is cooled to low temperatures to separate the lead alkyls.

cent by heating with zinc chloride at 300° to 400°C. for 6 hours.[102] Molybdenum sulphide at 410-420°C. causes considerable rearrangement in both *n*-heptane and *n*-octane, and at slightly higher temperatures (440°C.) the latter hydrocarbon also undergoes considerable cracking in addition to isomerization.

Octanes. According to Dintzes,[103] pyrolysis of *n*-octane and of 2,5-dimethyl hexane follows the reactions:

$$(1)\ C_8H_{18} \longrightarrow C_7H_{14} + CH_4 \qquad (3)\ C_8H_{18} \longrightarrow C_5H_{10} + C_3H_8$$

$$(2)\ C_8H_{18} \longrightarrow C_6H_{12} + C_2H_6 \qquad (4)\ C_8H_{18} \longrightarrow C_8H_{16} + H_2$$

In a copper-lined iron tube at 496-570°C. at normal pressure and with contact times of 6 to 130 seconds, equation (1) accounts for about 80 to 90 per cent of the total *n*-octane decomposed. Secondary reactions involving decomposition of the various olefins proceed to the extent of 60 to 70 per cent. Over this temperature range the energy of activation of *n*-octane is 64.5 kg.-cal. per mole and the primary dissociation constant is given by

$$\log_{10}k = 14.70 - \frac{14{,}100}{T} \pm 0.09$$

At 570°C. with contact times of 4 to 215 seconds, *n*-octane undergoes 5.7 to 61 per cent dissociation.[104]

2,5-Dimethylhexane, at 492-576°C. for 3 to 38 seconds, decomposes to the extent of 75 to 80 per cent according to equation (1), and the olefins undergo 50-70 per cent secondary decomposition.[105] The activation energy for the primary dissociation is related to the temperature by the equation:

$$\log_{10}k = 6.553 - \frac{7215}{T} \pm 0.05$$

Nonane. The pyrolysis of *n*-nonane at 670-750°C. results chiefly in the formation of pentene and butene, octene and methane, and hexene and ethane.[106] The primary reactions are further complicated by secondary olefin decomposition, as noted with the other normal paraffins cited.

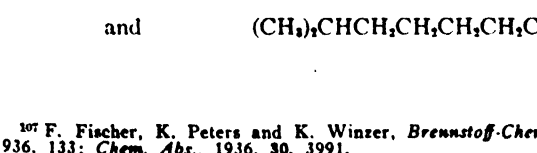
Higher Paraffins. Fischer, Peters and Winzer[107] decomposed Kogasin II (the higher boiling fraction of the liquid hydrocarbon mixture obtained by the Fischer-Tropsch process[108]) by immersing an electrically heated wire into the liquid. The products consisted of 20 per cent of a highly unsaturated light oil and 80 per cent of gaseous hydrocarbons, principally ethylene and its homologues. Other Kogasin fractions treated in this manner lead to similar results.

Under high pressure (110 to 265 atmospheres) of hydrogen, at 440°C. octadecane undergoes 88.5 per cent decomposition[109] yielding a continuous series of liquid products from pentane to heptadecane, the amounts of which decrease with increase of molecular weight. About 7 to 8 per cent of unsaturated compounds, small quantities of naphthenes and traces of benzene were obtained. The molecular yield[110] was 303 per cent, indicating that on the average each molecule was split twice. Gorniak and Szayna have obtained similar products with paraffin wax. At 440°C. the latter underwent 96.5 per cent decomposition with a molecular yield of 393 per cent, while at 446°C. the corresponding values were 98.6 and 465 per cent. With a rise in temperature the series of products contains an increased proportion of materials of low molecular weight at the expense of those of high molecular weight.

Catalytic Cyclization of Aliphatic Hydrocarbons

Moldavskii and Kamusher[111] report that when aliphatic hydrocarbons containing 6 or more carbon atoms are heated to 460-470°C. and passed over chromic oxide, they are readily transformed into members of the benzene series. Thus, *n*-hexane at 460°C., by undergoing ring formation and simultaneous dehydrogenation gave 17 per cent of benzene. At 470°C., *n*-heptane was converted into toluene (26 per cent). In the case of *n*-octane, however, at 460°C. the transformation followed two courses, resulting in the production of *o*-xylene (63 per cent) and small amounts of ethylbenzene. 2,5-Dimethylhexane and 2,7-dimethyloctane followed an analogous cyclization-dehydrogenation reaction, being converted into *p*-xylene (36 per cent) and *m*-methylisopropyl benzene (82 per cent), respectively, according to the equations:



and

[107] F. Fischer, K. Peters and K. Winzer, *Brennstoff-Chem.*, 1935, 16, 421; *Brit. Chem. Abs.* B, 1936, 133; *Chem. Abs.*, 1936, 30, 3991.

[108] This involves interaction of carbon monoxide and hydrogen. See Chapter 52.

[109] J. Gorniak and A. Szayna, *Przemysl Chem.*, 1934, 18, 57; *Chem. Abs.*, 1934, 28, 4876; *Brit. Chem. Abs.* B, 1934, 442.

[110] By molecular yield is meant the number of molecules obtained in reaction. Thus in this case, one molecule gave rise to 3.03 molecules, or on a percentage basis, 303 moles of products per 100 moles of octadecane reacting.

[111] B. L. Moldavskii and H. Kamusher, *Compt. rend acad. sci., U.R.S.S.*, 1936, 1, 355; *Chem. Abs.*, 1936, 30, 6713; *Brit. Chem. Abs.* A, 1936, 818; *Chem. Zentr.*, 1936, 1, 2339.

Octane and butylbenzene underwent similar changes, the former giving rise to *o*-xylene and the latter to naphthalene. The presence of olefins in the reaction mixture was also noted. This was attributed to the simultaneous dehydrogenation of the paraffins. Cyclization of a gasoline fraction was also attempted, but the reaction was found to be greatly complicated by the dehydrogenation of naphthenic hydrocarbons. Moldavskii and Kamusher also investigated the use of zinc oxide, alumina, nickel chromate, and uranium oxide and fluoride, and report that all of these were without catalytic activity. Molybdenum sulphide, however, acts similar to chromic oxide, but becomes deactivated much more rapidly than the latter.

MONOLEFIN HYDROCARBONS

Three main types of reaction can be discerned in the pyrolysis of monolefin hydrocarbons under conditions of limited decomposition, namely:

(1) Dissociation into hydrocarbons of lower molecular weight and hydrogen (true pyrolysis).
(2) Isomerization.
(3) Polymerization to yield hydrocarbons of higher molecular weight.

To emphasize the greater complexity encountered in the decomposition of unsaturated compounds compared with the corresponding saturated hydrocarbons, it should be remembered that paraffins undergo only the first two of these three transformations; the higher-boiling polymeric products are not generated from the latter except as secondary effects.[112] Paraffins do not show polymerization reactions because the temperatures for their decomposition to olefins are higher than those at which polymerization occurs.[113]

Frolich[114] has pointed out how exceedingly complicated the pyrolysis of a simple hydrocarbon such as propene may become because of secondary decompositions. It is practically impossible to include the reactions which the unsaturated constituents of all these secondary products may subsequently undergo, but the entire series of the primary compounds, most of which have been actually identified, can be explained on the basis of the Rice free-radical mechanism.[115] This reasoning explains why so many of the reactions appear to be non-reversible: although written as bimolecular for simplicity, in the light of the free radical changes involved they really become monomolecular. The fact that free radical collision is such an important factor helps to explain why diminished pressure and an equivalent dilution with inert material give such widely different results insofar as the product-consumption is concerned. Probability calculations will undoubtedly prove an aid to substantiate or disprove some of the reactions advanced.

Such variables as temperature, pressure, time of contact and catalysts seem to have a more profound influence on polymerization than on cracking. It may be possible, by proper choice of conditions, to favor the formation of one or more of the cracking products at the expense of the others, but the basic decomposition reactions remain more or less unaltered, according to Frolich.[116] In the case of polymerization the course of the reactions (and therefore the products formed) may be entirely governed by the operating conditions. Low-temperature catalytic treatment gives primarily an olefin with some degree of branchiness. Increase in both temperature and pressure causes a growing tendency for ring closure with the corresponding formation of naphthenic structures. Increase in temperature alone permits additional hydrogen to split off with simultaneous ring formation, yielding aromatic type products. Although analytical methods are not so well developed that it is possible to identify all of the polymerization compounds and account for the composition of the entire product, certain typical substances can be isolated in sufficient quantities to substantiate his general conclusion.

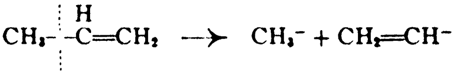
[115] See F. O. Rice and K. K. Rice ("The Aliphatic Free Radicals," The Johns Hopkins Press, Baltimore, 1935, Chapter 8) for a discussion of this theory.

[116] P. K. Frolich, *loc. cit.*

The more probable reactions in the decomposition of propene have been outlined by Frolich. Simple dehydrogenation gives propadiene:

$$(1)\ C_3H_6 \longrightarrow C_3H_4 + H_2$$

Scission of the carbon-carbon bond would result in the formation of methyl and vinyl radicals, as



$$CH_3-\vdots-\overset{H}{C}{=}CH_2 \longrightarrow CH_3^- + CH_2{=}CH^-$$

Either of these radicals may be expected to have a strong tendency to saturate itself by removing a hydrogen atom from the other. On transfer of 1 hydrogen to the vinyl radical, ethylene is formed, while at the same time the methylene residue may attach itself to a propene molecule, giving butene:

$$CH_2^- + C_3H_6 \longrightarrow C_4H_8$$

with an over all effect:

$$(2)\ 2C_3H_6 \longrightarrow C_2H_4 + C_4H_8$$

On the other hand, if the methyl radical succeeds in capturing a hydrogen atom, methane and acetylene become the products:

$$(3)\ C_3H_6 \longrightarrow CH_4 + C_2H_2$$

However, acetylene is extremely unstable so that Frolich believes it reasonable to assume that the primary acetylene residue will strive to combine with a molecule of propene with the formation of pentadiene:

$$\begin{aligned} C_2H_2^- + C_3H_6 &\longrightarrow C_5H_8 \\ \text{or}\ (4)\ 2C_3H_6 &\longrightarrow CH_4 + C_5H_8 \end{aligned}$$

which is evidently quite a prominent reaction. Still another possibility is for the primary radicals to react with themselves to give ethane and butadiene:

$$\begin{aligned} 2CH_3^- &\longrightarrow C_2H_6 \\ \text{and}\ 2C_2H_3^- &\longrightarrow C_4H_6 \end{aligned}$$

or an over all effect:

$$(5)\ 2C_3H_6 \longrightarrow C_2H_6 + C_4H_6$$

If scission of the double bond occurs, a different pair of radicals result:

$$CH_3CH{=}\vdots CH_2 \longrightarrow CH_3CH^- + CH_2^-$$

which might react with propene to form butene and pentene as:

$$(6)\ 3C_3H_6 \longrightarrow C_4H_8 + C_5H_{10}$$

Finally, polymerization of propene would explain the presence of hexene:

$$(7)\ 2C_3H_6 \longrightarrow$$

Unfortunately, the necessary experimental data to substantiate all of these reactions is lacking. However, Frolich has applied this method of reasoning to the results obtained by Schneider and Frolich[117] in the decomposition of propene at 725°C. and 0.2 atmosphere, as is shown in Table 18.

TABLE 18.—*Decomposition Products of Propene at 725°C. and 0.2 Atmosphere.*

[a] Roughly estimated.

[b] By difference between analysis for total CH_4 and that required to satisfy Reaction (3).

[c] By difference between analysis for total "C_5 and C_6 unsaturates" and that required to satisfy Reactions (4) and (6).

As to the relative stability of the olefins towards decomposition at 600 to 700°C., **Egloff** and Parrish[118] estimate them to be in the following descending order: ethylene, propene, isobutene, 2-butene, 1-butene, trimethylethylene, 2-pentene and 1-pentene.

Egloff and Wilson[119] state that the nature of the reaction products is dependent upon temperature, pressure and contact time. The energy of activation is an important guide to possible reactions at a given temperature, but there is no corresponding guide for the effects of pressure. The simple relation of a change in volume during a reaction measures only effects due to large variations in pressure. Although the latter greatly influence the nature of the substances formed, the exact relationships remain to be found. For a given temperature and pressure the contact time determines the actual products obtained.

Polymerization of an olefin to nonaromatic compounds occurs at the initial temperatures of reaction. The relative ability of a particular olefin to polymerize will depend on its structure. In general, points of unsaturation are conducive for this action, provided the unsaturated carbon atoms are not too highly substituted with methyl or ethyl groups.[120] Points of unsaturation also promote isomerization and since these particular reactions have low energies of activation, the most favorable conditions are low temperatures and long contact times.[121]

With respect to catalysts, it has been pointed out[121a] that the characteristic action of such substances on olefins is the formation of carbon and hydrogen. However, liquid products may be obtained when sodium, iron, cobalt, copper, nickel or Ascoloy is employed. Reduction in activity is observed when deposition of carbon on the contact agent occurs or when the latter forms stable compounds with the hydrocarbons undergoing treatment. Of the alloys studied, Monel metal, Chromel (nickel and chromium) and Alumel (nickel, iron and silicon) promoted decomposition of the olefins into carbon and hydrogen.

ETHYLENE

Egloff and Wilson conclude that ethylene may be regarded as the basic hydrocarbon in thermal reaction. The key to the decomposition of most hydrocarbons can be found in a study of ethylene since the latter is an important product below 750°C. and above this temperature the resultants are essentially all derived from it. This olefin undergoes five main types of transformation, (1) polymerization, (2) hydrogenation to ethane, (3) scission of one carbon-hydrogen bond, (4) scission of the double bond and (5) dehydrogenation to acetylene, and these are shown in Fig. 20. The principal products obtained at normal pressure[122] and the approximate temperature ranges for their initial appearance and maximum formation are listed in Table 19.

TABLE 19.—*Pyrolytic Products of Ethylene.*

Product	Temperature, °C. Initial Formation	Temperature, °C. Maximum Formation
Butane, butenes	350-400	650-750
Ethane	450-500	700
Methane	500	1000
Acetylene	650-700	1400
Aromatics	650	800-850

Hurd and Eilers[123] have investigated the effect of various tube surfaces on the decomposition of ethylene in the range of 550-800°C. Ascoloy (a steel containing 24-30 per cent of chromium), quartz and Pyrex tubes were found to be noncatalytic, while iron effected considerable carbonization. See Table 20.

1100°C. in the presence of 2 per cent of mercury or cadmium vapor.[125] A yield of 2 to 4 per cent of butadiene has been obtained at 700-750°C. by using a silica tube packed with copper gauze.[126] Five consecutive separations and recirculations of the gas lead to 9-10 per cent conversion to the diolefin along with some aromatic hydrocarbons. Greater rate of flow increased the formation of butadiene at the expense of the aromatics. Diminished pressure had no effect on the butadiene yield.

pressure with very short contact times. At the lower temperature, acetylene and hydrogen are the principal products, together with smaller amounts of paraffins. Longer periods of contact favor higher yields, amounting to 21 and 48.4 per cent for acetylene and hydrogen, respectively, and 14.2 per cent for paraffins at 0.044 second. Formation of butadiene (about 1.5 per cent) and propene and butenes (3.0 per cent) is not greatly influenced by the contact time. At 1400°C., the results differ radically, in that no di- or monolefins (except ethylene) are found, the reaction being chiefly one of dehydrogenation to acetylene. Table 21 is a summary of the data obtained under these conditions.

PROPENE

The two most probable types of decomposition for propene are (1) into hydrogen and an allyl radical and (2) into methyl and a vinyl radical. Rice[128] estimates the energy of activation for these two transformations to be 91,000 and 85,000 cal., respectively. Dissociation begins at 350°C., slightly lower than for ethylene, as might be expected from the asymmetry of the molecule. The thermal reactions of propene[129] are summarized in Fig. 21.

Travers[130] has shown that at 550°C. in the presence of hydrogen, decomposition is principally to ethylene and methane, while at the same time hexenes and pentenes are formed by the condensation of molecules of propene alone and with ethylene.

That the type of surface plays an important part in the pyrolysis of propene has been noted by Hurd and Eilers.[131] Monel metal is extremely destructive in its action, causing intense carbonization even at 350°C. Ascoloy (a chromium steel) is practically non-catalytic, and iron is intermediate between the two, as summarized in Table 22.

FIG. 21.—Thermal Reactions of Propene. (G. Egloff and E. Wilson)

Observations of pyrolysis at 1100°C. and low pressures (50 mm.) in conjunction with short contact times show that lower paraffins (methane and ethane), ethylene, acetylene, hydrogen and small amounts of butadiene are formed.[132] At 1400°C. and the same pressure, propene is completely decomposed, hydrogen and acetylene resulting mainly. Butadiene is produced in small quantities but its formation is entirely suppressed at contact times greater than 0.0022 second. Data obtained in this investigation are summarized in Table 23.

BUTENES

The thermal decomposition of the *n*-butenes is a complex process in which polymerization, isomerization and splitting of the carbon chain take place simultaneously. Because of the symmetry of the molecule, 2-butene is the more stable, initial decomposition occurring at 350°C., while with 1-butene the temperature is 25° lower. Since either of the two isomerizes into the other, a study of one is really a study of a mixture of both, according to Egloff and Wilson.[133] Only at low temperatures in the early stages of the decomposition will differences due to the relative stability of the two appear.

Figs. 22 and 23 are graphical representations of the reactions undergone together with the calculated energy of activation. The products from 1-butene may be accounted for by reactions (1), (2) and (7) (Fig. 22) and from 2-butene by (1) and (2) (Fig. 23) although the exact mechanism is unknown. Absence of other possible radicals may be attributed to the fact that such radicals tend to undergo very rapid secondary reactions giving a more stable form.

Wheeler and Wood[134] have found that cyclohexene, cyclohexadiene, methylcyclohexene and methylcyclohexadiene are the chief polymerization products below 650°C., while above this temperature aromatic compounds predominate in the liquids obtained. This is very unusual, as 8-carbon-molecule polymerization products might be expected. However, the formation of the 6- and 7-carbon molecules shows that the free radicals from the primary dissociation, and not the butene molecule as a whole, are polymerized.

The catalytic rearrangement of the *n*-butenes has been studied by Ipatieff, Pines and Schaad.[135] In the presence of orthophosphoric acid, 1-butene undergoes 4 per cent isomerization at 26°C. and 60 per cent at 135°C. A catalyst of diatomaceous earth impregnated with phosphoric acid gives complete conversion to 2-butene at 249°C. and 7.8 atmospheres pressure. Pure *trans*-2-butene underwent rearrangement to the extent of 6.6 per cent to 1-butene and 6.0 per cent to *cis*-2-butene when passed through orthophosphoric acid at 100°C. Aqueous solutions of perchloric acid (70-72 per cent) and benzene sulphonic acid (75 per cent) were also found to effect the transformation of 1-butene, the first giving 21 per cent isomerization at 21°C. and the latter 13 per cent at 76°C.

FIG. 22.—Thermal Reactions of 1-Butene. (G. Egloff and E. Wilson)

Hurd and Goldsby[136] have stated that extensive rearrangement of the gaseous decomposition products of the *n*-butenes occurs at 650°C. The ratio of *cis* to *trans* forms[137] in 2-butene was found to be practically unchanged in the pyrolysis of the latter, indicating that the stereoisomers share equally in whatever changes occur. However, more *cis* than *trans* isomer was found in the 2-butene produced from 1-butene.

The kinetics of the isomerization of *cis*- and *trans*-2-butene at 345-390°C. have been investigated by Kistiakowsky and Smith,[138] who report that the equilibrium mixture consists of 52.8 per cent *trans* compound at these temperatures. Although there was no evidence to indicate polymerization or formation of 1-butene, the mechanism of the reaction is thought to involve a chain because of the abnormalities observed.

High yields of butadiene have been reported[139] from pyrolysis of 2-butene diluted with an inert gaseous material at about 700°C. Passage of a 7 to 1 mixture of nitrogen and the hydrocarbon through a porcelain tube at this temperature gave a 21 per cent yield of the diolefin with 18-24 per cent decomposition of the butene.

Pyrolysis at 1100°C. in conjunction with low pressure and short contact times is reported to favor the formation of butadiene from both normal butenes.[140] In the case of 1-butene, lower paraffins, hydrogen, acetylene and ethylene are all found in appreciable quantities, as would be expected in accordance with Reactions (1), (2) and (7) (Fig. 22). At 1400°C. with 1-butene, only hydrogen, acetylene and paraffins are obtained in large proportions at contact times greater than 0.0036 second, showing the dominance of Reaction (2). The large yield of acetylene may be attributed to the fact that at this temperature, acetylene formation from ethylene reaches a maximum.[141] In no test, however, was any isobutene obtained. The data for these hydrocarbons are incorporated in Tables 24 and 25.

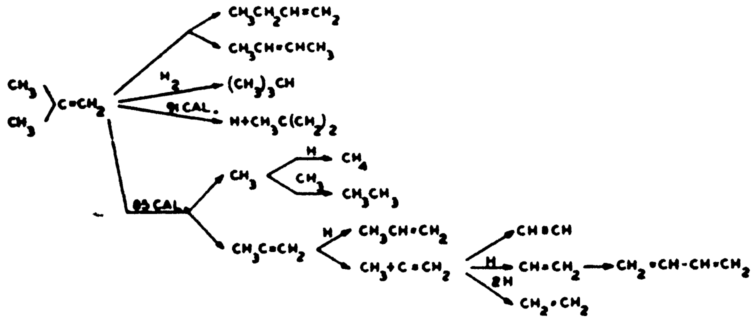
ISOBUTENE

The thermal reactions of isobutene differ from those of the normal butenes or straight-chain olefins. As a result of its unsymmetrical character, the molecule will tend to form more stable substances, either by losing the methyl groups or by adding hydrogen. The latter change and also the formation of propane are favored by relatively low-temperature treatment, and use of higher temperatures is marked by the increase in yields of acetylene and methane.[142] The thermal reactions for isobutene are shown in Fig. 24.



Courtesy Industrial and Engineering Chemistry

FIG. 24.—Thermal Reactions of Isobutene. (G. Egloff and E. Wilson)

Hurd and Eilers[143] have studied the thermal decomposition of this hydrocarbon both from the standpoint of primary products and of catalytic influence of different tube materials. The results of their experiments at temperatures of 700-800°C. are shown graphically in Fig. 25, in which the composition of the gaseous products is compared at various percentage conversions. Extrapolation to zero conversion would seem to indicate that methane, propene and ethylene are the important primary gaseous products, while hydrogen and acetylene are not.[144] Hurd and Eilers, however, believe that ethylene is not actually an initial product but is probably a secondary one derived from propene. An examination of the liquid obtained in pyrolysis at 700°C. showed the following substances: (in per cent) trimethylethylene, 1.2; benzene, 10.3; toluene, 11.8; unsaturated oil b.p. 78-125°C. (diisobutene?), 22.1; naphthalene, 8.75; anthracene, 3.0; unsaturated oils b.p. 125-190°C., 19.5; residue, 23.4. A number of comparative experiments in tubes of different materials show that Ascoloy (a chromium steel alloy), quartz and glass have little influence on the decomposition at 700°C. Monel metal and iron, particularly the former, favor considerable carbonization and entirely suppress oil formation. Similarly, nickel at 700°C. inhibits the production of oil but its catalytic action is less marked than with Monel and iron. Table 26 lists the data obtained in these tests.

shows the importance of the relation of structure to decomposition products. In the case of the branched hydrocarbon, the production of paraffins (mostly methane), acetylene and hydrogen predominate whereas ethylene, which was major resultant in the normal compounds is relatively unimportant. The yield of butadiene is quite good, but is slightly below that obtained with the other two butenes.

HIGHER MONOLEFINS

It has been shown by Hurd, Goodyear and Goldsby[146] that partial isomerization of 1-pentene into 2-pentene, and vice versa, takes place during the pyrolysis of these hydrocarbons at temperatures above 580°C. at atmospheric pressure. The gaseous products from both pentenes consisted of methane, 1-butene, propene, ethane and ethylene in the molar proportions 6, 2, 2, 2, 1, respectively. In addition, small amounts of 2-butene, butadiene and hydrogen resulted. 2-Pentene was found to be somewhat more stable than 1-pentene under these conditions.

[146] C. D. Hurd, G. H. Goodyear and A. R. Goldsby, *J.A.C.S.*, 1936, **58**, 235; *J. Inst. Pet. Tech.*, 1936, **22**, 255A; *Brit. Chem. Abs.* A, 1936, 451; *Chem. Abs.*, 1936, **30**, 2911.

The pyrolysis of 2-pentene in glass, Ascoloy and iron tubes at 560-700°C. has been investigated by Hurd and Eilers.[147] In iron tubes, pronounced carbonization with total suppression of oil formation occurred even at 560°C. Ascoloy did not appear to catalyze the decomposition to any appreciable extent. In glass or Ascoloy tubes at 600-700°C. the main gaseous products were methane, ethane, propene and butenes, with only small amounts of hydrogen. The butene fraction consisted principally of 1-butene, with smaller amounts of 2-butene, isobutene and butadiene. Benzene, toluene and various unsaturated hydrocarbons were contained in the liquid fraction.

Isomerization of 1-hexene has been shown to take place by heating at 400°C. and 140 atmospheres pressure for 1 hour, giving rise to 2-hexene and 3-hexene, but no isohexenes. In the presence of molybdenum sulphide, 1-hexene commences to polymerize at 350°C. and normal pressure.[148] The thermal decomposition of 1-hexene in an excess of water vapor at 550-700°C. has yielded 40 per cent ethylene, 30 per cent propene and 4.3 to 5.8 per cent butadiene. Like treatment of 4-methyl-1-pentene gave 58-60 per cent propene.[148a]

When *ter*-butylethylene is heated to 160-170°C. in the presence of floridin, it is converted into tetramethylethylene, according to Lebedev and Kudrjavtzev.[149] At 150-270°C. *ter*-butylmethylethylene changes into trimethylethylethylene under the influence of this catalyst, while *ter*-butylacetylene, tetramethylethylene and trimethylethylethylene are unaffected by similar treatment, even up to 300°C.

Lebedev and Slobodin[150] found that the passage of diisobutylene over a floridin catalyst at 205-210°C., at a velocity of 0.4 to 0.45 g. per minute, resulted in a yield of 70 per cent of diisocrotyl (2,5-dimethyl-2,4-hexadiene). Hurd and Eilers[151] have pyrolyzed both technical diisobutylene (a mixture of 2,4,4-trimethyl-1-pentene and 2,4,4-trimethyl-2-pentene) and pure 2,4,4-trimethyl-2-pentene in Pyrex tubes at 700°C. The pure hydrocarbon decomposed more rapidly than the technical mixture and furnished a gas containing large portions of isobutene. The mixture, instead, yielded a gas consisting chiefly of methane and hydrogen, with only 5 to 8 per cent of isobutene. The liquid products showed the formation of small amounts of aromatic hydrocarbons (much less than in the case of isobutene under similar conditions) and also large proportions of unsaturated liquids with boiling ranges both below and above that of the diisobutylene used. Hurd and Eilers concluded that diisobutylene need not be regarded as an essential intermediate in the thermal polymerization of isobutene.

Certain large molecular weight monolefins with highly branched chains undergo cleavage under special conditions with the production of a mixture of lower olefins. Nazarov[152] has studied the splitting of several of these hydrocarbons, including di-*ter*-butylethylene, under the influence of 1-bromonaphthalene-4-sulphonic acid and similar acids. Unsymmetrical dimethylethylene is the chief product, with smaller amounts of tetramethylethylene, isopropylmethylethylene and *ter*-butylethylene.

Pinene. Thermal decomposition of turpentine oil, which consists mainly of two isomeric dicyclic monolefins, is of interest since it has been used as a source of isoprene. Mahood[153] noted that a maximum yield of isoprene of about 4.5 per cent may be obtained by pyrolysis in a Pyrex tube at 600°C. and in an iron tube at 450°C. Finely divided copper has been recommended as a catalyst for decomposition to aromatics (which may consume as high as 31 per cent of the pinene) at 500 to 630°C.[154] Toluene, *m*-xylene, cymene, cumene and methylethylbenzene have been obtained in this fraction. Nickel causes an energetic reaction at 600°C. with the deposition of much carbonaceous material, a gas rich in hydrogen and but little liquid. Cobalt is intermediate between copper and nickel in its action, but iron resembles nickel and causes intense carbonization.

DIOLEFINS

Extensive information on the thermal reactions of diolefins is apparently not available. The lowest member of the series (allene, $CH_2{=}C{=}CH_2$) is an isomer of both methylacetylene and cyclopropene. Isomerization of these three hydrocarbons, involving the shifting of hydrogen atoms in the molecule (which requires only a small energy of activation), should occur at low temperatures.[155] Likewise, because of the unsaturated nature of the series, polymerization of the diolefins should be expected, since the double bonds are conducive to this type of reaction, provided the compounds are not of high molecular weight.[156]

Slobodin[157] reports that methylallene begins to isomerize at 250°C. under the influence of activated floridin, and at 330°C. undergoes 24.5 per cent rearrangement. The products obtained at the higher temperature were 20.6 per cent bivinyl and 3.9 per cent ethylacetylene ($C_2H_5C{\equiv}CH$). Dimethylacetylene was not detected, nor were any traces of dimers of bivinyl or methylallene. Unsymmetrical dimethylallene with activated floridin at 334°C. gives isoprene and isopropylacetylene, $(CH_3)_2CHC{\equiv}CH$, in 20.8 and 60 per cent conversions, respectively. Partial polymerization may also take place; resulting chiefly in a dimer of isoprene.[158]

Lebedev and Slobodin[159] obtained a 41.5 per cent yield of dipropenyl by 6 recirculations of diallyl (1,5-hexadiene) over a floridin catalyst at 225°C. The isomerization was accompanied by a partial polymerization of the hydrocarbons.

ACETYLENE

According to Egloff and Wilson, the reactions of pure acetylene should differ considerably from those observed with this hydrocarbon when it is a secondary decomposition product of ethylene. The reason for this is probably because of the small concentration of acetylene molecules in the latter instance, due to the dilution with other molecules. Dissociation should take place through the same mechanisms, but the chances for methenyl (CH≡) radical formation are much greater.[160] Aromatic hydrocarbons, carbon, hydrogen and methane are the main products at 650°C. or over.[161]

Because of its highly unsaturated nature, acetylene polymerizes very readily in the range of 400° to 800°C. Mignonac and Ditz[162] obtained, along with other products, two gases corresponding to the empirical formula of butenyne (C_4H_4) by passing acetylene rapidly through a narrow-bore silica tube at 750°C. The gases were cooled to —70°C., and liquefied, one into a colorless stable carbide (having the above formula), and the other into a substance known as chlorene (a polymer of C_4H_4), a greenish-yellow gas, which on standing was converted into the first. These substances may be linear polymers of the type obtained by Mignonac and de Saint-Aunay[163] by the action of the electric discharge on acetylene at low temperatures.

Travers[164] found that at 450°C. the addition of hydrogen to acetylene greatly influences the rate of reaction. Large concentrations of hydrogen suppress the formation of ethylene but do not change the yield of methane. The reaction velocity is decidedly affected by the surface conditions, as in the case of ethylene and ethane.

Aromatics have been obtained in good yields by Klatt[165] by passage of acetylene diluted with 10 per cent of steam through a porcelain tube at 650 to 700°C. and atmospheric pressure. Several runs were made, using coke, graphite, porcelain and earthenware fragments as packing, but the maximum conversion to liquids resulted with contact material consisting of graphitic carbon deposited on pieces of clay plate. Fujio[166] likewise reports good yields of aromatics by passing acetylene through an iron tube lined with silicon or an alloy of chromium and silicon, heated to about 650°C.

CYCLIC HYDROCARBONS

Of the monocyclic saturated hydrocarbons those containing the cyclopentane and cyclohexane rings are by far the most heat-stable and differ greatly from the corresponding paraffins in this respect. This property complicates the study of primary reactions, since the initial products may be decomposed even under conditions where little of the cycloparaffin is converted.[167]

However, the lower members of the series, such as cyclopropane and cyclobutane hydrocarbons, exhibit a tendency to undergo rupture of the ring, especially with the aid of such catalysts as alumina, at relatively low temperatures with the formation of the corresponding straight-chain olefin. Cycloparaffins of more than 6 carbon atoms are less stable than cyclopentane and cyclohexane.[168] Cyclohexane derivatives are characterized by the fact that with such catalysts as nickel

[161] It has been shown by A. V. Frost (*Khimteoret, Leningrad*, **1935** (2), 98; *Chem. Abs.*, 1935, **29**, 5626) that whereas synthesis of acetylene from its elements sets in above 2500°K. (2227°C.), the formation of this hydrocarbon from others proceeds at much lower temperatures, at which acetylene is thermodynamically unstable.

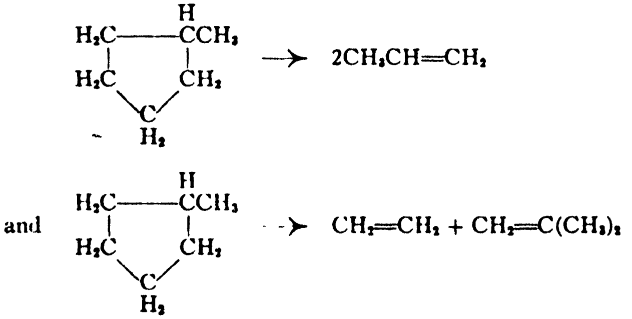
or palladium they can be dehydrogenated to the corresponding aromatic hydrocarbons and that this process is reversible.[169]

Cyclopropane. Chambers and Kistiakowsky[170] have investigated the kinetics of the thermal isomerization of cyclopropane into propene in a static system over the range 470-519°C. The reaction was found to be homogeneous and apparently unimolecular, the relation between the high-pressure velocity constant and temperature being represented by the equation:[171]

$$\log_{10} k = 15.17 - \frac{65{,}000}{2.3RT}$$

Cyclopentane. The results obtained by Frey[172] indicate that this hydrocarbon undergoes decomposition in a silica tube at 575°C. at a rate only about one-sixth as great as that of *n*-pentane under the same conditions. At 574°C. and a pressure of 67 mm., with a contact time of 10 minutes, the dissociation amounted to 22 per cent, and from 100 moles of cyclopentane there were produced (in moles): hydrogen, 23; methane, 5; ethylene, 20; ethane, 2; propene, 27; propane, 2; cyclopentadiene and cyclopentene, 16; and higher hydrocarbons, 6. It appears, therefore, that the two main reactions involved are (1) dehydrogenation to cyclopentene and cyclopentadiene, and (2) rupture of the carbon ring to form ethylene and propene. Kazanskii and Plate[173] substantiate this mechanism by a study of the pyrolysis at 590-800°C. in silica tubes using contact times of 0.5 to 20 seconds.

Methylcyclopentane. In the decomposition of this hydrocarbon at 650°C., Kazanskii and Plate[174] obtained gaseous products consisting chiefly of propene with some isobutene. The content of saturated hydrocarbons was higher than in the gas produced by pyrolysis of cyclopentane, probably as a result of the splitting of methane from some of the products. The two main reactions appear to be:



Other Cyclopentane Derivatives. Although in the presence of aluminum chloride, containing small amounts of water, methylcyclopentane is readily converted into cyclohexane,[175] even at low temperatures, when passed over platinum charcoal (18 per cent Pt) at 310-350°C., as noted by Nenitzescu and Cioranescu,[176] the former hydrocarbon is unchanged. Likewise, Tarasova[177] states that neither the ethyl, propyl, butyl, 1,2-dimethyl, 1-methyl-2-ethyl nor 1-methyl-2-propyl derivatives of cyclopentane are dehydrogenated in the presence of platinum charcoal in a stream of hydrogen or carbon dioxide even at 300°C.

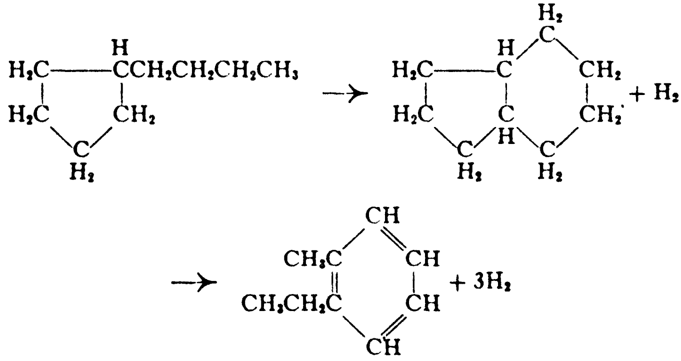
On the other hand, the work of Zelinskii, Kazanskii and Plate[178] shows that methyl, ethyl and propyl-cyclohexane are readily converted into members of the paraffin series in the presence of hydrogen and platinized charcoal at 305-315°C. The reaction involved is thought to consist only of opening the ring, resulting in the formation of both normal and isoparaffins. Decomposition of the two lower members of the series was not believed to be of a complicated nature, because of the boiling range of the reaction mixture. However, from propylcyclopentane, appreciable quantities of lower molecular weight hydrocarbons were obtained. Subsequent investigations[179] with *n*-butyl-, *sec*-butyl- and isoamyl-cyclopentanes show that under the same conditions, not only paraffins but also aromatics are formed. In fact, aromatization could still be distinctly detected while hydrogenation to paraffins occurred to only a slight extent. Kazanskii and Plate point out that although the aromatic hydrocarbons might have been formed by expansion of the ring at the expense of the side chain, yet, if this is the mechanism involved, then it is difficult to understand why methylcyclopentane and the other lower homologs failed to undergo transformation to aromatics. They therefore suggest another possibility, that is, that a 6-membered ring is formed by closure of the butyl side chain, with the resulting hydrindane then changing into *o*-methylethylbenzene with the opening of the 5-membered ring, as for example:



The first mechanism mentioned above, that involving ring enlargement, should give only monosubstituted derivatives, whereas the latter (involving the rupture of the cyclopentane ring) would form disubstituted benzene homologs. A study of the products obtained from butylcyclopentane showed that the principal resultant was a methylethylbenzene, with a small amount of a monosubstituted aromatic, which upon oxidation gave benzoic acid. A branched paraffin, thought to be 4-methyloctane, was also isolated from the reaction mixture.

Denisenko[180] has investigated the stability of phenylcyclopentane at 300-310°C. in the presence of platinized active charcoal (12 to 15 per cent Pt) and hydrogen. He reports that under these conditions the 5 membered ring is ruptured more readily than is cyclopentane. From the composition of the reaction mixture, which contained 1-phenylpentane (amylbenzene), 2-phenylpentane and 3-phenylpentane, the formation of these substances is explicable on the basis that the ring splits between the 1,2- 2,3- or 3,4- carbon atoms accompanied by the addition of one molecule of hydrogen. Such a transformation may be illustrated as follows:

Cyclohexane. Catalytic dehydrogenation of cyclohexane to benzene proceeds smoothly when aided by such metals as nickel or palladium.[181] With a nickel-alumina catalyst at 200-270°C., the energy of activation is about 13,600 cal. per mole for the dehydrogenation of both cyclohexane and methylcyclohexane, although the reaction is much more rapid in the latter case.[182] It has been noted, however, that with the latter catalyst at 330-350°C., cyclohexane in the presence of hydrogen undergoes a peculiar conversion with the formation of not only benzene but also methane, toluene, xylene, methyl- and dimethylcyclohexane. Ipatieff and Komarewsky[183] have identified biphenyl among the reaction products. Zelinskii and Shuikin[184] believe that in addition to undergoing dehydrogenation to benzene, part of the cyclohexane decomposes to form methylene radicals, which are either reduced to methane or combined with benzene and unchanged cyclohexane.

Balandin and Brussov[184a] point out that there are two classes of catalysts in this reaction. Such metals as platinum, palladium and nickel at about 300°C. cause dehydrogenation of 6-membered rings to aromatic nuclei. Oxides of chromium, molybdenum and zinc, employed at 450°C., may give intermediate products, such as cyclohexene or cyclohexadiene.

There is ample evidence to prove that, in the purely thermal decomposition of cyclohexane, direct dehydrogenation to benzene is not the primary process. Butadiene and ethylene appear to be the most important products, although these may subsequently be converted into aromatic hydrocarbons by secondary reactions. Thus, Zelinskii, Mikhailov and Arbuzov[185] pyrolyzed cyclohexane, admixed with an excess of steam (1.5 to 4 volumes), to obtain at 750°C. a molar conversion of 92 per cent to ethylene and 39.9 per cent to butadiene. Kazanskii and Plate[186] reported that at 650°C. in silica tubes the gaseous products were mostly hydrogen, lower paraffins, ethylene and a little isobutene. Whitby and Katz[187] cite a 60.8 per cent conversion to butadiene (based on cyclohexane decomposed) by noncatalytic processes.

By treatment of cyclohexane at 622°C. and 68 mm. pressure, Frey[188] obtained 24 per cent decomposition. A mixture of liquid and gaseous products had the following percentage molar composition: hydrogen, 8.1; methane, 3.3; ethylene, 8.4; ethane, 3.7; propene, 5.6; butadiene, 5.6; butenes, 5.0; pentenes, 1.6; unchanged cyclohexane, 57.0; hexenes and hexadienes, 2.1; higher hydrocarbons, 0.5; and benzene, 0.4. It is evident that under these conditions, benzene production is almost negligible and that hydrogen, ethylene, butadiene and butenes are the main reaction products.

On the other hand, chromium-copper catalysts at 500-550°C. are said to cause only dehydrogenation, forming 80 per cent aromatic compounds.[189] Other catalysts, for example, alumina, alumina-zinc chloride and alumina-phosphoric acid are less effective, giving rise to some gaseous and liquid saturated and unsaturated hydrocarbons and partly isomerized paraffins.

Investigations on the decomposition of cyclohexane at 600 to 700°C. indicate that the compound is progressively dehydrogenated, first to tetrahydrobenzene (cyclohexene), then to dihydrobenzene (cyclohexadiene) and finally to benzene itself.[190] Decomposition of the tetrahydrobenzene may also proceed in another manner to yield butadiene and ethylene. The formation of naphthalene in this reaction is believed to be the result of polymerization and condensation of free radicals formed in the energetic decomposition of the cyclohexane.

Other Cyclic Hydrocarbons. Relatively high conversion of both saturated and unsaturated cyclohydrocarbons into butadiene and isoprene has been obtained by pyrolysis of these hydrocarbons admixed with steam as diluent.[191] For example, the yields of butadiene (expressed as molar percentages of the hydrocarbons decomposed) from methylcyclohexane, ethylcyclohexane and decalin at 750°C. were 34.8, 41.2 and 11.6, respectively. Cyclohexene at 650°C. gave molar yields of 78.3 per cent ethylene and 65.2 per cent butadiene, whereas 1-methylcyclohexene at 690°C. furnished 75.1 mole per cent ethylene and 35.3 mole per cent isoprene.

Ethylcyclohexane undergoes decomposition similar to that of cyclohexane in the presence of a nickel oxide-aluminum contact agent at 350°C., according to Ipatieff and Komarewsky.[192] Benzene, toluene, methane and hydrogen were found in the reaction mixture.

The dimethylcyclohexanes have been pyrolyzed at 675-750°C. in the presence of 2 to 4 times their weight of water by Arbuzov and Mikhailov.[193] Conversions to butadiene, in mole per cent of the hydrocarbon decomposed, were: from 1,2-dimethylcyclohexane, 20.7; from 1,3-dimethylcyclohexane, 18.4 and from 1,4-dimethylcyclohexane, 23.9. Large amounts of ethylene, propene and butene and saturated hydrocarbons were also obtained.

Levina and Tzurikov[194] found that vinylcyclohexane when passed over a palladium asbestos catalyst at 200°C., was converted into ethylbenzene and ethylcyclohexane. Analogous to this, allylcyclohexane gave propylbenzene and propylcyclohexane under the same conditions. Subsequent investigations[195] show that the isomers allylcyclohexene, cyclohexylallene and cyclohexylallylene when contacted

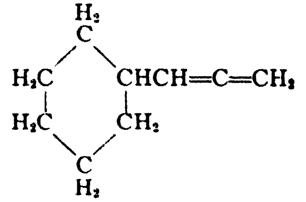
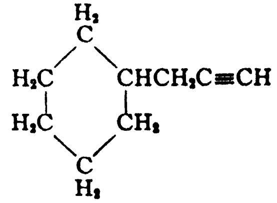
allylcyclohexene



cyclohexylallene



cyclohexylallylene

with platinum-carbon agents (containing about 30 per cent Pt) at 200-205°C. in a weak current of carbon dioxide are completely decomposed into identical products of irreversible catalysis, namely, 35 per cent propylcyclohexane and 65 per cent propylbenzene. The mechanism of the conversion is explained by isomerization with a transposition of the double bond into the ring, thus forming an intermediate cyclohexene or cyclohexadiene structure, which immediately undergoes further reaction. The acetylenic side chain is believed to isomerize to the allene type, and then react as above.

The dehydrogenation of 7- and 8-carbon rings to aromatic hydrocarbons has been investigated by Ruzicka and Seidel.[196] Using selenium or palladium charcoal, at 390-440°C. cycloheptane was readily converted into toluene, and cyclooctane to *p*-xylene. The mechanism may have involved ring opening followed by closure to a smaller ring or by closure followed by cleavage. Heating methylcycloheptane with selenium for 27 hours at 440°C. resulted in the production of a mixture of ethylbenzene and *o*- and *p*-xylene. The formation of these substances is explicable on the basis of rupture of the 7-membered ring and subsequent closure between the various positions relative to the attached methyl group. Treatment of 1,1,4-trimethylcycloheptane gave *p*-methylethylbenzene and 1,2,3-trimethylbenzene, whereas 1,1,4-trimethylcycloheptene under similar conditions formed a hydrocarbon which, on oxidation with potassium permanganate, gave isophthalic acid (indicating a 1,3 structure).

Selenium and palladium charcoal are said to be very effective in causing ring increments, especially in the case of a 6-carbon ring from a cyclopentane derivative, as is evidenced from the ready conversion of 1- or 2-methylhydrindene into naphthalene at 450°C. with these catalysts.[197] Likewise naphthalene can be obtained from 1- and 2-ethylhydrindene, 1-*iso*-octylhydrindene and methylisopropylhexahydrofluorene or 1,2-diethylcyclohexene-1 with selenium at 420°C. The yields of naphthalene varied from 5 to 50 per cent and were generally twice as great with selenium as with palladium. The methyl derivatives give the largest proportion of naphthalene, and, in general, the conversion to aromatics decreases with increased complexity of the hydrocarbon. However, at temperatures above 350°C., secondary reactions, such as those involving the cleavage of alkyl chains, become quite prominent. In view of this decomposition, Ruzicka and Peyer point out that at temperatures in excess of 400°C., the results obtained in the aromatization of cyclopentane derivatives require careful interpretation. Nenitzescu and Cioranescu[198] also report the formation of amounts of naphthalene from both 1-methylhydrindene and 1-methylhexahydrohydrindene using platinum charcoal at 310-350°C. By passing indene or hydrindene over dehydrogenating catalysts, such as magnesia, or magnesia-zinc oxide, at 500-750°C., chrysene is said to result.[199]

Aromatic Hydrocarbons

The aromatic hydrocarbons as a class are characterized by high thermal stability. On pyrolysis, they tend to yield more complex aromatic hydrocarbons with the liberation of hydrogen. Rupture of the aromatic ring does appear to take place to some extent, and aliphatic side chains (if present) are usually split off.[200]

Benzene. The statement that the thermal decomposition of benzene is a homogeneous reaction[201] is not substantiated by the kinetic measurements of Mead and Burk,[202] who studied the decomposition at 750 to 852°C. in a silica tube. The heterogeneous nature of the reaction was demonstrated by the increased reactivity when using a tube packed with quartz, but the change in rate was not proportional to the variation in surface. Filling the tube with steel chips caused a larger amount of decomposition than would normally have been expected. The velocity data were accommodated by the equation:

$$kt = \frac{x}{a - x} + 2.3 \log\left(1 - \frac{x}{a}\right)$$

which suggested that this decomposition is a bimolecular surface reaction strongly retarded by the products. The apparent energy of activation is about 50,000 cal. Mead and Burk noted that the materials formed consisted of hydrogen, acetylene, small amounts of other unsaturated gases and methane, biphenyl, *p*-diphenylbenzene and a few higher condensation products. The ratio of weight of gaseous products to weight of solids lessened with increasing partial pressure of benzene at a given temperature but carbon deposition was slight even at 850°C.

The production of biphenyl by pyrolysis of benzene is of technical interest.[203] The yield may be increased by the use of elevated pressures, amounting to about 4 to 5 per cent at 440-450°C. under 170 atmospheres pressure.[204] Catalysts such as nickel and iodine are favorable, a concentration of 6 per cent of the latter giving a 14-17 per cent conversion at 420-440°C. and 125 atmospheres. Iron and nickel are said to be superior to brass, aluminum, copper and chromium for this reaction at 470°C., a 0.5 per cent conversion being obtained with the first two.[205] High pressures of hydrogen inhibit the reaction. In no case was hydrobiphenyl detected, but the deposition of soot shows that some carbonization was undergone as a result of the catalytic action of these metals.

Other Aromatic Hydrocarbons. The results of Pease and Morton[206] indicate that the lower aromatic hydrocarbons may be listed in the following order of decreasing thermal stability at 630°C.: *o*-xylene, toluene, benzene, *m*-xylene, and ethylbenzene. A study of the decomposition of the latter hydrocarbon from the kinetic standpoint showed the reaction at 540-580°C. to be homogeneous and pseudo-unimolecular.[207] The velocity constants for the dissociation of ethylbenzene in this temperature range can be accommodated by the equation:

$$\log_{10} k = 15.01 - \frac{70{,}000}{2.3RT}$$

which is almost identical with the corresponding one for the dissociation of ethane.[208] Examination of the products of decomposition of ethylbenzene at 550-600°C. showed that, at small conversions, hydrogen and styrene[209] are the main products. The gaseous hydrocarbons contained small amounts of lower olefins, methane and ethane. These products are accounted by the following reactions:

$$\begin{array}{lll}
(1)\ C_6H_5C_2H_5 & \longrightarrow & C_6H_5CH{=}CH_2 + H_2 \\
(2)\ C_6H_5C_2H_5 & \longrightarrow & C_6H_6 + C_2H_4 \\
(3)\ 2C_6H_5C_2H_5 & \longrightarrow & C_6H_5CH_2CH_2C_6H_5 + CH_4 \\
(4)\ 2C_6H_5C_2H_5 & \longrightarrow & C_6H_5C_6H_4C_2H_5 + C_2H_6
\end{array}$$

of which the first is thought to be the most important. An 82.7 per cent yield of styrene was obtained by Zal'kind and Bulavsky[210] by passage of ethylbenzene diluted with nitrogen over a catalyst of 10 per cent zinc oxide and 90 per cent alumina at 660-670°C. under a pressure of 10 to 13 mm. With nickel oxide-alumina, however, the decomposition of ethylbenzene follows a different course. Thus with this material at 350°C., Ipatieff and Komarewsky[211] identified hydrogen, methane, ethane, benzene, toluene and naphthalene, but no styrene.

Baddeley and Kenner[212] decomposed *p*-xylene by passing it through a silica tube heated to 800°C. Benzene, toluene, 2,6-dimethylanthracene and a small amount of *m*-xylene were obtained. Under similar conditions, 2,6-dimethylanthracene yielded benzene, toluene, naphthalene and anthracene, but apparently no *m*- or *p*-xylene.

Hurd and Bollman[213] have examined the products of pyrolysis of *o*- and *p*-allyltoluenes at 600-700°C. in a quartz tube. The gas was principally methane with a considerable quantity of hydrogen and olefins, ethylene predominating in the latter. The liquid obtained consisted of toluene, *o*- and *p*-xylene, naphthalene and traces of benzene. The results seem to indicate that alpha bonds are more resistant to heat than the beta bonds. Although 4-phenyl-1-butene is less stable than *o*-allyltoluene, it could not be isomerized to the latter hydrocarbon.

---

[207] A pseudo-unimolecular reaction is a special type of decomposition represented by the general equation:

$$A + B \longrightarrow C + D$$

in which the substance B is a catalyst, or is present in high concentration as compared with A, so that its concentration will not change appreciably throughout the experiment, thus giving the effect of a unimolecular reaction. See F. O. Rice and H. C. Urey, "Reaction Velocity in Homogeneous Systems," in H. S. Taylor, "A Treatise on Physical Chemistry," D. Van Nostrand Co., Inc., New York, 1930, 959.

[208] Pease and Morton give the equation

$$\log_{10} k = 15.12 - \frac{73{,}200}{2.3\,RT}$$

Chapter 3

Cracking Processes and Some of Their Products

The term "cracking" is commonly used to denote the conversion of petroleum fractions to motor fuels through the application of heat and pressure.[1] The production of optimum yields of high grade gasoline from various crudes or their fractions is the aim of practically all of these operations, although there are exceptions to this generalization.[2] Egloff, Crandal and Doty[3] remind us that kerosene, gas oil, fuel oil, tractor fuel, furnace oil, Diesel oil, road oil, asphalt and high grade coke may also be produced in these operations. According to Auld[4] cracking is not only a method for augmenting the proportion of gasoline obtainable from crude oil, but it is "one of the most important means we have for adjusting the yields of the various products of petroleum to meet the ever-changing demands of the market."

Investigations in the field of cracked gasoline have been promoted largely by the demands for 100-octane fuel desired by the aviation and automotive industries. As a result, isooctane, which formerly cost $20 a gallon and was used only for the standardization of the antiknock ratings of secondary fuels, is now being produced in substantial quantities at a comparatively low price level. The effect of this development is shown not only in the increase in automobile top speed from 60 miles per hour in 1925 to over 100 in 1936, and in the cruising speed of airplanes from 80 to 260 miles per hour over the same period, but also in the gain in power output of 20 to 30 per cent for 100-octane fuel over 87-octane commercial gasoline. The latter fact is important in the field of aviation as this reduction in fuel consumption permits the transportation of larger pay loads.[5] The enormous scale on which the cracking industry is conducted has also led to the production of another type of motor fuel, "polymer gasoline," which is prepared from cracking gases. A discussion of this topic will be considered subsequently under polymerization.[6]

The importance of cracked gasoline can be readily ascertained from Table 28,

TABLE 28.—*Production of Motor Fuel in the United States in Thousands of Barrels (42 gallons) and Per Cent of Total.*

	1933		1934		1935

[6] See Chapter 26.

which shows the production of motor fuel from the three major sources in the United States during 1933, 1934 and 1935. The quantity of cracked fuel amounts to approximately 44 per cent of the total output, and is just slightly under the production of the straight run fuel.[6a] However, in 1934 the cracking processes led to a conservation of 792 million barrels of crude oil, or 46.92 per cent of the total crude oil consumed.[6b] In this respect, a 13.7 per cent increase in the output of cracked gasoline during 1935 as compared with 1934 is noteworthy.

[6b] G. Egloff, E. E. Crandal and M. M. Doty, *loc. cit.* See also *Oil & Gas J.*, 1936, 34 (35), 22.

Although the United States produces almost 80 per cent of the total world supply of cracked gasoline, the advances made in other countries during 1935 were quite significant, according to Egloff, Crandal and Doty. They summarize the reasons for the increased capacity in other countries as: (1) refiners have realized that balanced operation necessitates the inclusion of cracking, (2) the demand for motor fuel is constantly increasing and (3) higher antiknock-rating fuels are desired. The distribution of the cracking capacity of the world is shown in Table 29. It will be seen that the output of the Dutch West Indies (which ranks second) is less than 4 per cent of the total, or about one-twentieth of that of the United States. Canada, Russia, Iran (Persia), France and Argentina are the only other important producers, and their total is only about 11 per cent of the figure for the world.

Egloff and Nelson[7] have pointed out that the cracking processes employed during 1935-6 are highly flexible in their application. Due to the introduction of multiple heating coils, different time-temperature-pressure conditions dependent upon the nature of the cracking stock are possible. Furthermore, these are not limited to the production of gasoline. A large variety of liquid fuels, ranging from kerosene to fuel oil, can be made, depending upon the operating conditions.[8] Whereas in 1913 cracking runs of 2 days' duration were considered maximal, units now in use are capable of operating continuously over spans of more than 150 days.

The Thermodynamics of Cracking[8a]

A study of the thermodynamics of cracking leads to several interesting conclusions. Considering the thermal cleavage of the members of the paraffin series, two types of reaction are possible: dehydrogenation and true chain rupture. Schultze[9] has represented the variation of free energy change with temperature and composition for these two types of reaction (under equilibrium conditions) by the equations,

(1) $$C_nH_{2n+2} = C_nH_{2n} + H_2; \quad \Delta F = 33400 - 27.9T - (500 + T)n$$

and

(2) $$C_{(m+n)}H_{2(m+n)+2} = C_mH_{2m+2} + C_nH_{2n}; \quad \Delta F = 18700 - 26.9T - (500 + T)n$$

In order for reaction (1) to take place at 400°C. (673°K.), that is, to give negative value for the free energy change, the molecules must be of the size of dodecane ($n = 12$) or tridecane ($n = 13$). Similarly, dehydrogenation of heptane to heptene should occur only at temperatures in excess of 600°C. On the other hand, reaction (2) is thermodynamically possible for all paraffins above propane at the temperatures encountered in commercial cracking (390-630°C.) and is much the more probable of the two. The peculiarity of the latter reaction is that only the size of the olefin molecule produced and the temperature are decisive for evaluating the free energy change in this case. However, even the most improbable case, involving the formation of a large paraffin molecule along with a small olefin molecule, is thermodynamically more favored than dehydrogenation according to equation (1). In addition, it will be noted that there are several possibilities as to the nature of the decomposition into complementary olefins and paraffins, as given

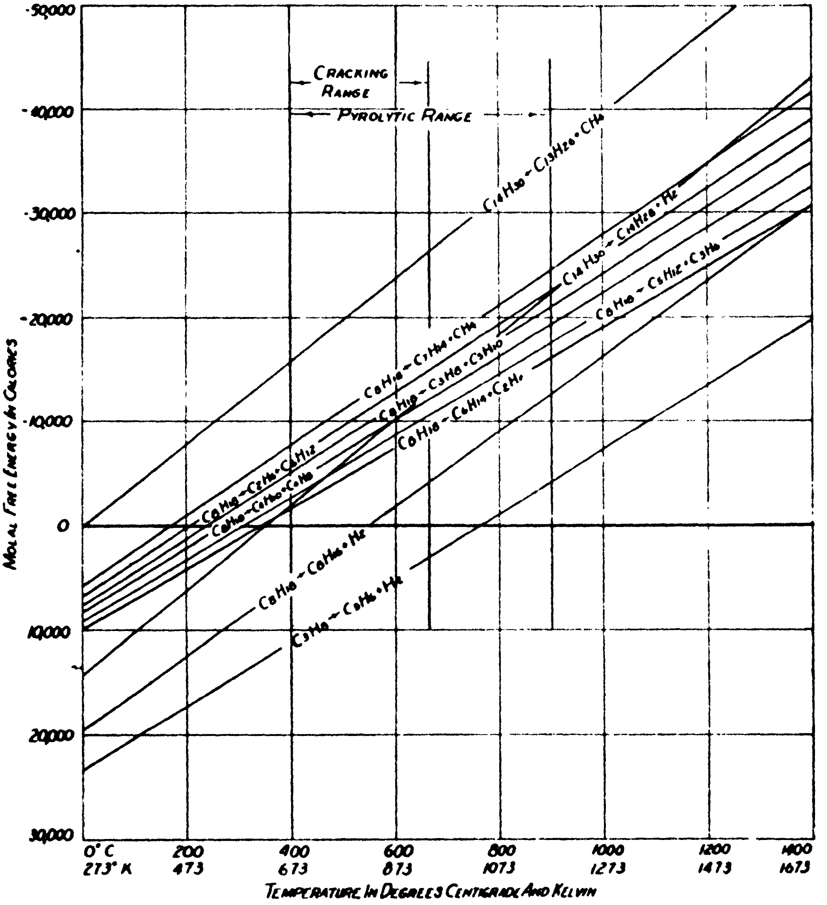

FIG. 26.—Variation of Molal Free Energy with Temperature for Typical Cracking Reactions.

by the expression $(m + n - 2)$. The limiting case for the dissociation is when m is equal to unity (corresponding to methane).

Fig. 26 is a graphical representation of equations (1) and (2) using tetradecane ($C_{14}H_{30}$), octane and propane as examples. In the ordinary range of temperatures used in commercial cracking (390-630°C.) the ΔF values obtained from equation (2) for the decomposition of tetradecane to methane and tridecene and of octane (all six possibilities of this hydrocarbon) are decidedly negative, indicating that all paraffins higher than heptane or octane will readily tend to crack to lower molecular weight products. Dehydrogenation of tetradecane is also possible, but that of octane is quite improbable except at temperatures above 600°C. Under these conditions, propane should not be expected to undergo dehydrogenation but will break down to give methane and ethylene. However, at temperatures of about 900°C., such as those encountered in pyrolysis, dehydrogenation of these paraffins (especially the higher molecular weight members of the series) does become a prominent type of decomposition, although the thermodynamic tendency is still not as high as that for the rupture of the chain.[9a]

Demethylation, that is, the case in which the olefin resulting from the rupture of the original molecule is as large as possible, is the type of splitting best favored thermodynamically. This theoretical conclusion tends to be confirmed by the presence of methane as the major ingredient of cracking gases. According to Schultze such deductions are in complete agreement with Haber's cracking rule,[10] which states that of the two molecules formed in the cleavage of a paraffin, the smaller should be paraffinic and the larger olefinic. However, the differences in the free energy changes for the various possibilities for the fracture of a molecule (at a given temperature) are so small that by the application of pressure the breaking point in the molecule may be shifted. Following LeChatelier's principle, the application of pressure should favor the formation of products having the lowest vapor tension. In this case the resultants would be those compounds formed by central fracture.

Schultze has also demonstrated the impossibility of the immediate formation of condensation products from paraffins according to the reaction:

$$\mathrm{mC_nH_{2n+2} = C_{mn}H_{2mn+2} + (m-1)H_2;} \quad \Delta F = (m-1)(14{,}700 - T)$$

This reaction is unfeasible at any temperature. When condensation products are formed, Schultze believes that they result indirectly from the decomposition of olefins.

The dimerization of olefins according to the scheme:

$$\mathrm{2C_nH_{2n} = C_{2n}H_{4n};} \quad \Delta F = -18{,}700 + 26.9T$$

is interesting because, as the first approximation, the free energy is independent of the size of the olefin molecule. Above 425°C., however, depolymerization occurs, but this tendency for decomposition may be retarded by the application of pressure. Likewise, disproportionation according to the equation:

$$\mathrm{C_{m+n}H_{2(m+n)} = C_mH_{2m+2} + C_nH_{2n-2};} \quad \Delta F = 34500 - 33.7T + (500 - T)n$$

yielding one molecule of a paraffin and one of an acetylene hydrocarbon, is probable at temperatures above 800°C., in the case of propane. Similarly, the formation of naphthenes by condensation of ethylene is quite likely at low temperatures, especially under high pressure.[11]

According to Parks and Huffman,[12] at temperatures below 500°K. (237°C.) paraffins and cycloparaffins are more stable than olefins and aromatics. At higher temperatures, however, this stability is reversed and olefins and aromatics become the more permanent hydrocarbons. Thus, Schultze[13] shows that the dehydrogenation of cyclohexane to benzene should be expected at temperatures above 200°C. In both cycloparaffin and aromatic hydrocarbons having long side chains, the tendency is towards splitting off the chain rather than rupturing the ring.

[9a] It should be borne in mind that such high temperatures, though attainable in the laboratory, are not employed in commercial cracking operations.

KINETICS OF THE CRACKING PROCESS

In the early stages of reaction and at small percentage decomposition, cracking of pure hydrocarbons and also petroleum fractions follows a unimolecular law. However, at more pronounced cracking, secondary reactions, involving the interaction of the primary products, proceed to a marked extent. Many of the latter reactions and also the dimerization of olefins are of a bimolecular nature.[14] This fact greatly complicates a study of the rates of reaction. Dintzes, Eshevskaya and Klabina[15] have reported that the velocity of the cracking reaction is practically independent of the degree of cracking or duration of the reaction, provided the percentage decomposition is kept small. Their experiments were carried out with various petroleum fractions, using a vapor-phase cracking system. The extent of decomposition in all cases was limited to 10 or 15 per cent.

The influence of temperature on the velocity of the cracking reaction is expressed by the integrated form of the Arrhenius equation,

$$\log_e K = \frac{-E}{RT} - C$$

where K is the monomolecular velocity constant, E is the energy of activation, R, the gas constant (1.985 cal. per degree), T, the absolute temperature (°K.), and C is the integration constant. (The important physico-chemical constant, E, the activation energy of the reaction, must be clearly differentiated from the heat of reaction.) The energies of activation of a wide variety of pure hydrocarbons[16] and of various petroleum fractions in both liquid and vapor phase processes have been determined, and although these values may be fairly close to one another, they are by no means identical.

For the formation of gas, gasoline and coke from gas oil, Geniesse and Reuter[17] found a value of E equal to 53,400 cal. On the other hand, Keith, Ward and Rubin[18] obtained 57,100 cal. for E, considering only the formation of gas and gasoline. Huntington and Brown[19] report values of E and C of 59,200 cal. and 32.55, respectively, for the commercial production of gas, gasoline and coke from a feed stock containing 75 per cent of recycle material, and having an A.P.I. gravity of 24.8 at 60°F. A critical review of this question has been contributed by Obryadchikov[20] who concludes that the energy of activation is higher for light products and lower for heavier ones. He also states that aromatic fractions require a higher degree of activation than paraffins of the same molecular weight. The activation energy of cracked naphtha is lower than that of straight-run naphtha. However, this condition is reversed for heavier hydrocarbon fractions.

The actual data for E are higher when gasoline is taken as the sole product than when all the decomposition products are included in the calculation.[21] The temperature coefficients of cracking velocity are naturally in the reverse order of the activation energies, being lower for the lighter fractions than for the heavier ones and also lower for aromatic charging stocks than for paraffinic ones. A value of $E = 65{,}800$ cal. per mole has been found by Lederer[22] for the cracking of a paraffin base oil at 450°C. and of mazout at 425°C.

On the basis of experiments with various hydrocarbons, Pease and Morton[23] suggested that the ratio of the energy of activation to the integration constant of the Arrhenius equation was a constant. This view has been discussed by Dintzes, Eshevskaya and Klabina[24] who found that the values of the ratio varied from 4.16 to 4.94. These same investigators report that individual narrow cuts of straight-run Grozny and Baku petroleums of boiling ranges 100-270°C. are characterized by activation energies varying between 46,000 to 54,000 cal.

In general, the cracking process is decidedly endothermic, although certain of the reactions involved, such as polymerization, are actually exothermic. On account of its complex nature, the heat of reaction of a cracking operation depends greatly upon the degree of cracking as well as upon the character of the charging stock. In this respect, Butkov and Chechkina[25] have stated that when cracking a Baku kerosene distillate feed at 20°C., the following heat input is required: 941-944 cal. per kg. if cracked at 625°C., 1052-1095 cal. at 675°C. and 1284-1337 cal. at 725°C.

FUNDAMENTAL FACTORS INFLUENCING CRACKING

The fundamental variables in all types of cracking operations are temperature, time of reaction, pressure and the character of the charging stock. Although catalysts naturally affect the velocity and course of cracking, their influences are generally of secondary importance. This topic will be considered subsequently in this chapter. In addition to the four variables mentioned above, it is necessary in industrial operations (involving recycling) to specify another factor, the conversion per pass, or the extent to which the reactions are allowed to proceed before the products are separated from the cycle stock which is returned to the system. Although this quantity is a function of the other variables, its influence on the characteristics of the operation is best considered independently.[26]

Temperature variations affect both the velocity of the cracking reaction and also the nature of the hydrocarbons formed. Thus, high-temperature (1000°F.) treatment results in high olefin and aromatic content liquids. On the other hand low-temperature (750-850°F.) cracking furnishes principally paraffinic and naphthenic hydrocarbons.

The velocity of cracking depends markedly upon the temperature of the reaction. Expressing the rate of change of the velocity with respect to temperature by the Arrhenius equation and integrating between temperature limits gives the relation:

$$\log_e \frac{k_2}{k_1} = \frac{E}{R}\left(\frac{T_2 - T_1}{T_2 T_1}\right)$$

where k_1 and k_2 are the velocity constants at the absolute temperatures T_1 and T_2, respectively, E is the energy of activation in calories, and R is the gas constant (1.985 cal. per °K.). For an increase of 10°C. (18°F.) the velocity constant is doubled at room temperatures. However, at the temperatures encountered in cracking, this approximation is often not very accurate. Egloff and Nelson[27] report that the rate is doubled by a rise of 21°F. at 800°F. and 26°F. at 900-950°F. The variation of cracking velocity with temperature is also dependent upon the character of the charging stock. In general, lighter fractions have lower temperature coefficients than the heavier fractions, so that a smaller increase in temperature is sufficient to double the reaction velocity in the former case. Obryadchikov[28]

FIG. 26A.—Effect of Time and Temperature on Gasoline Yields in Cracking Crude Oils. (A. W. Trusty)

reported that in reforming[29] of a gasoline, requiring an activation energy of 70,000 cal. per mole, at 400°C. the reaction will be doubled for a 9°C. rise in temperature, and at 500°C., for a 12°C. rise.

The effect of temperature and time in cracking gas oil has been discussed by Trusty.[30] At about 800°F., a 10 per cent yield of gasoline is obtained with a heating time of 30 minutes, but at 890°F. this may be accomplished in 10 seconds. Similarly, to form 30 per cent gasoline at 800°F. requires about 2 hours heating, yet at 890°F. the time is reduced to less than 3 minutes.

In commercial cracking units, the time element varies considerably. High temperature operation (say at 1100°F.), as exemplified by the Gyro vapor-phase unit, is usually carried out with heating times of 1 to 2 seconds. Vapor-phase processes operating at 825°F. ordinarily employ an average of 15 to 20 minutes for an 18 per cent yield of gasoline, according to Trusty.[31] However, for mixed-phase processes at 900°F., the same conversion is obtained in 1.5 to 2 minutes. On the other hand, with low temperature operation (about 820°F.), as with the Cross, Dubbs or Tube and Tank units, the reaction time is generally in the magnitude of 20 minutes and may even be as long as 6 hours.

Geniesse and Reuter[32] have shown that the influence of both time and temperature on the yields of cracked products (i.e., the conversion per pass) may be expressed as a composite variable, termed the "time-temperature index." Arbitrarily taking 480°C. as the standard cracking temperature, and assuming that the rate of cracking is doubled for a 17°C. rise, the time-temperature index, Θ, is given by the relation:

$$\Theta = 2^{x}t$$

where $x = \dfrac{T - 480}{17}$, T is the cracking temperature, °C., and t is the time of contact in minutes. For a given charging stock the extent of cracking is approximately the same for a given value of the time-temperature index. In effect, this means that analogous results may be obtained by cracking at low temperatures with long contact, or at higher temperatures in corresponding shorter heating times. On the basis of this index, Turner and LeRoi[33] have correlated octane number improvement in naphtha reforming under high pressures at temperatures up to 1025°F. These investigators used approximately the same reference temperature, 900°F. (482°C.), however they assumed that the velocity of reaction doubles for a 25°F. rise in temperature. The corresponding value of x in this case is

$$x = \frac{T - 900}{25}$$

where T is the temperature in °F. From experimental data obtained in reforming both straight run and cracked naphtha in a Tube and Tank unit, these investigators arrived at an empirical relation between the octane number and Θ (the equivalent seconds at 900°F.) as shown in Fig. 27. Thus, if it was desired to improve the octane number of a naphtha from 60 to 70 by reforming, the time necessary for the operation was estimated from this chart by taking the difference between the abscissae corresponding to the above octane number ordinates (that is, 560 — 200 = 360 seconds, required in this case). The average deviation from these values was found to be about 1 octane number. Turner and LeRoi state that variations in pressure, temperature and charging rate exerted no apparent influence on the results. In their opinion, equivalent time[34] is the decisive factor in determining the detonating quality of the reformed gasoline.

---

[29] The term "reforming" is used to denote the cracking of naphthas and low grade gasolines to produce higher octane number motor fuels.

[33] S. D. Turner and E. J. LeRoi, *Ind. Eng. Chem.*, 1935, 27, 1347; *Chem. Abs.*, 1936, 30, 275; *J. Inst. Pet. Tech.*, 1936, 22, 20A; *Brit. Chem. Abs.* B, 1936, 178; *Nat. Pet. News*, 1935, 27 (24), 30; *J. Inst. Pet. Tech.*, 1935, 21, 339A.

The results of Schutt[35] on the influence of various factors on the vapor-phase cracking of oils indicated that the ratio of gas to gasoline in the products could not be correlated with the time-temperature index. The octane number of the product was a function of the temperature, but was not particularly related to the time factor or recycle rate. The temperature was also considered by Sydnor[36] to be the controlling factor for determining the octane number in mixed phase cracking at 860-900°F. under 200 lbs. per sq. in. pressure. On the other hand, Keith, Ward and Rubin[37] concluded that the temperature had apparently no effect on the octane number but that the latter was closely related to the conversion per pass.

Pressure. Sachanen and Tilicheyev[38] reported that pressure has no substantial influence on either cracking or on the character of the product obtained. The primary reaction taking place during the destruction of the hydrocarbon chain is of a monomolecular type, consequently the application of pressure (i.e., the concentration of the reacting molecules in the reacting zone) should not affect its velocity. Nemtzov,[39] however, does not agree with the above conclusions of

---

[34] In this case, the term "equivalent time" refers to the amount of time (in seconds) required at 900° F., which may be obtained from the time-temperature curve on the assumption that the cracking rate doubles with a 25° F. rise in temperature.

[39] M. S. Nemtzov, *J. Inst. Pet. Tech.*, 1935, 21, 644; *J. Inst. Pet. Tech.*, 1935, 21, 375A; *Brit. Chem. Abs.* B, 1935, 836; *Chem. Abs.*, 1935, 29, 6410.

Sachanen and Tilicheyev. From the results of high pressure cracking experiments, he states that not only the character of the resultants but also the reaction velocity is dependent upon the pressure. The olefins formed in the cracking operation have a tendency to polymerize, and since polymerization reactions are bimolecular, they will be favored by the application of high pressure. For instance, in the case of simple dimerization the rate of the reaction is proportional to the concentration of the reacting molecules and, therefore, the square of the pressure. Because of this fact, the products obtained by cracking under high pressures should contain much larger proportions of polymerized olefins than the corresponding low pressure treatments.

One direct effect of pressure, according to Nemtzov,[40] is the increased yields of gasoline in place of gases. The suppression of gas formation by higher pressures is in accordance with the observations of Keith, Ward and Rubin, who found that the gas yield varied inversely as the pressure.[41] Their conclusions were based on data obtained by cracking gas oil at 800-1100°F. under pressures of 100 to 1000 lbs. per sq. in.

That the pressure exerts a considerable influence on the character of the product has also been noted by Trusty.[42] The readily condensable hydrocarbons, particularly the diolefins, are polymerized under pressure and are eliminated from the gasoline in the form of high-boiling heavy residues. The stability of the liquid products, with respect to gum formation, is thus greatly increased. As an example, gas oil cracked at 1075°F. under 15 lbs. per sq. in. pressure resulted in a gasoline with a gum content of 600 mg. per 100 cc. (copper dish method), whereas, when operating under 100 lbs. per sq. in. at the same temperature, the gum value was reduced to 100 mg. per 100 cc.

Sydnor[43] observed that distinctly higher yields of gasoline are obtained at low than at higher pressure for operations carried out at the same temperature. The data obtained in his experiments with a Mid-Continent gas oil of 33.7° A.P.I. gravity, using a Tube and Tank unit, are given in Table 30. Both at 860 and 900°F. conversion to gasoline was decreased about 10 per cent by an increase in pressure from 200 to 750 lbs. per sq. in. However, the formation of gas and coke was decreased by the application of higher pressures.

TABLE 30.—*Effect of Pressure on Cracking Gas Oil Using Tube and Tank Unit.*

Pressure, lbs. per sq. in.	200	200	200	750	750	750	750

Octane number of gasoline, CFR. method	63.5	69	69	—	—	67	69.6

Trusty[44] has summarized the advantages of the use of pressure as (1) better conditions for heat transfer, (2) absence of local overheating and (3) increased yield of gasoline products.[45]

Character of Charging Stock. The character of the charging stock is of much greater importance in influencing the yields of products of mixed-phase rather than of vapor-phase cracking. In the case of vapor-phase treatment, Trusty states that the character of the charging stock has no effect. Wagner,[46] however, disagrees with this observation on the basis of data obtained by vapor-phase cracking at 1100°F. and low pressure (50 lbs. per sq. in.). The analysis of the exit gases from the cracking operations under these conditions, using three different charging stocks, is given in Table 31. Acording to Wagner, the variation in the composition of these gases is illustrative of the corresponding changes in the liquid product. The increase in the per cent of methane and hydrogen (perhaps due to splitting of side chains from ring compounds) with increased carbon-hydrogen ratio in the feed stock is very marked. The corresponding decrease in the percentages of both ethylene and propene is also noteworthy.

C_4 fraction	4.7	6.4	7.4
C_5 fraction and heavier	3.1	2.5	2.3

Aleksandrov[47] found that the gasoline yield could be increased by cracking narrow petroleum cuts under different thermal conditions. Low-boiling fractions gave optimum results when treated at high temperatures with long heating periods. High-boiling fractions, however, produce best yields of motor fuels when cracked at low temperatures with short times of contact.

Trusty[48] has shown that the chemical composition of the charge is quite important in determining the operating conditions. Since the paraffin hydrocarbons crack more readily than any other group, paraffinic base oils should be the easiest to decompose. The paraffins between dodecane ($C_{12}H_{26}$) and cetane ($C_{16}H_{34}$) are the most stable of these hydrocarbons. However, the stability decreases with the paraffins of higher molecular weight. The resultants of the cracking of paraffins are smaller paraffins and olefins. Naphthenes are more heat resistant than the paraffins and are dehydrogenated to aromatics during cracking. Cyclic hydrocarbons may occur in the feed stock or may be formed in the course of the reactions by polymerization of olefins resulting in the decomposition of the paraffins. Aromatics, however, require heating to a high temperature before undergoing rupture. The differences in the ease of cracking straight run gas oil and cracked gas oil are very marked and may be attributed directly to the difference in the chemical nature of these two substances. The former oil is of a paraffinic nature and tends to undergo decomposition quite readily. The latter oil, which is recovered from the reaction mixture of the straight run gas oil, is much more on the aromatic side and is considerably harder to crack.

Effect of Conversion Per Pass. The extent to which the cracking reactions are allowed to proceed before the tarry bodies and gasoline fractions are separated from the recycle oil is known as the conversion per pass. Sydnor[49] defines this quantity as the product of the percentage gasoline and the percentage fresh feed. Most cracking systems involve recycling or the return of a portion or all of the heavier residual oil produced to the feed stock, generally straight-run distillates. In these systems, the total feed rate (straight-run plus cycle oils) is maintained constant, and the quantity of straight-run gas oil added per unit of time must be the equivalent of the total material removed from the system in the form of gasoline, fuel oil, cycle gas oil, gas and coke. Keith and Montgomery[50] have stated that increasing the conversion per pass results in (1) a lower total yield of gasoline, (2) gasoline of a higher octane number, (3) a greater gas production and (4) an increased tendency toward coke formation.

This factor is important because, if the cracking is carried out too far, the heavy residues will form coke. However, by removing the products from the zone of reaction and separating the objectionable materials, undesirable residues can be avoided to a large extent. In fact, only a limited amount of gasoline can be formed in each cracking stage.[51] The actual degree of cracking is, therefore, dependent upon the type of charging stock.[52] Thus, with a paraffinic base oil, a conversion per pass as high as 20 to 25 per cent can be used without excessive coke formation. On the other hand, with asphaltic base stocks this value should not exceed 10 to 15 per cent.[53] Dobryanskii, Kanep and Katzman have stated that too high a conversion per pass tends to "burning" the paraffinic constituents and condensing them to the more stable cyclic compounds.[54]

The diminution in the gasoline yield with increasing conversion is attributed primarily to the decomposition of the product already formed. According to Sachanen[55] the decomposition of the gasoline is negligible with conversions up to 20 per cent. However, for a 50 per cent possible yield per cycle the actual quantity of gasoline obtained is only about 41 per cent, the remaining 9 per cent being cracked to still lower molecular weight hydrocarbons.

Significance of Coke Formation in Cracking. The reactions involved in the cracking of an oil are of a progressive type. The resultants (e.g., gas, gasoline, intermediate oil, tar, coke and residue) do not form simultaneously during the breaking up of the original hydrocarbons. Especially in the case of coke formation, decomposition appears to proceed through the stages of intermediate oil, tar and finally coke.

However, as shown previously, coke will not be formed unless the conversion per pass is carried out beyond a definite point. This limit is determined by the composition of the compounds in the charging stock. Due to the fact that asphaltic base oils naturally contain tars, coke formation sets in more rapidly in this case than when cracking a paraffin base or a distilled oil.[56] Coke does not result from the primary decomposition of paraffins. On the other hand, a high temperature is required to crack the aromatics, and all of the coke formation is said to be traceable directly to this class of hydrocarbons. Hence the more aromatic the stock is initially the greater will be the proportion of coke. However, as was shown by Trusty in the case of cracked gas oil, coke can be obtained from an aromatic-free stock by prolonged heating which changes the nature of the stock to an aromatic type. Gerr[57] has suggested eliminating coke formation in high temperature vapor-phase cracking by vaporizing the oils and separating the vapors

from the residue in a step previous to the cracking. Light preliminary cracking in order to break down the heavy oil fractions has also been proposed to prevent excessive carbonization.[58]

Butkov and Ostrovai[59] reported that coke exerts a strong catalytic action on the secondary reactions in high temperature cracking. Condensation reactions, according to the views of these investigators, are heterogeneous and are catalyzed by the coke formed in the retort. Consequently a small amount of coke in the apparatus promotes higher yields of aromatic compounds. On the other hand larger quantities effect more pronounced condensation, which is accompanied by lower yields of aromatic compounds, gas and light oils. Heavy cracking carried out in a retort free of coke results in a low yield of aromatics and a high yield of gas. Butkov and Ostrovai have stated that the amount of coke produced in commercial cracking operations depends upon the stock and in general varies from 1.2 to 9 per cent.

CATALYSTS

A large number of substances have been suggested as promoters for the cracking of petroleum fractions.[60] Borisov and Gaverdovskaya[61] investigated the vapor-phase catalytic cracking of gas oil, kerosene and various hydrocarbons found in petroleum (such as hexane, cyclohexane, methylcyclohexane and dimethylcyclohexane). In these tests, zinc oxide, nickel oxide (Ni_2O_3), alumina, uranyl oxide (UO_3), titanium dioxide, thorium dioxide, nickel wire and nickel precipitated on alumina, activated carbon, activated bone charcoal, glass chips and fused borax were used. The best yield of gasoline from gas oil was obtained by cracking at 550°C. in the presence of nickel oxide and amounted to 38.0 per cent. Under the same temperature conditions without an activator, the conversion was only 18.2 per cent. In the case of kerosene, the effect of catalysts is even more pronounced. Pure thermal treatment at 500°C. gave a gasoline yield of 7.8 per cent. With uranyl oxide, the gasoline yield was increased to 26.4 per cent, and with activated carbon, 33.8 per cent. In the presence of uranyl oxide, branched cycloparaffins underwent demethanation in addition to dehydrogenation.

The use of coke formed in the reaction chamber as a catalytic agent has already been discussed. The action of a wide variety of forms of activated carbon has also been investigated. Morrell[62] suggested mixing finely divided solid bituminous material, such as coal or lignite, with the oil. The low-boiling products obtained by cracking this mixture are said to be of high antiknock value. Fields[63] has mentioned the addition of a small percentage of finely divided vegetable material, such as sawdust or beet pulp, to the oil. The suspension is heated to 750°C. to effect simultaneous cracking of the oil and carbonization of the solid material. Cotton wool may also be employed at temperatures of 300-350°C., according to Oppenheim.[64] Zurcher[65] proposes to utilize petroleum coke, activated by treatment with steam and phosphoric acid. Activated carbon, impregnated with a solution of potassium silicate, potassium carbonate, potassium chloride and potassium sulphate, or sodium carbonate and sodium chloride, and calcined has been found to be an activator for the cracking of mineral oils.[66] Zinc chloride may also be substituted as an impregnating agent.[67] Pier and Donath[68] prepare a catalyst by mixing ammonium vanadate, cobalt nitrate and phosphoric acid with activated charcoal and heating the resulting magma for about 6 hours in the presence of hydrogen and carbon disulphide at 350°C. This catalyst is recommended for reforming gasoline at temperatures of 430-450°C. Towne[69] has suggested the use of silica gel in which activated carbon is imbedded as a catalyst in treatments to increase the antiknock value of gasolines. In this case, however, the process is carried out at 500-700°C.

Lelgemann[70] has studied the catalytic action of nitrosyl chloride (NOCl) in conjunction with aluminum, iron, aluminum chloride, iron chloride and calcium oxide in cracking various petroleum fractions. In this treatment, the metallic promoter is added to the cracking stock and a small amount of nitrosyl chloride (about 0.1 per cent) is introduced continuously into the reaction chamber. Thus, by interaction with the nitrosyl chloride the activity of the metallic promoter is constantly regenerated. The proportions of solid catalyst are given as: with calcium oxide, 5 per cent; with powdered aluminum, about 0.08 per cent; with aluminum chloride, 7.4 per cent and with aluminum chloride and ferric chloride together, 12 per cent. Gifford[71] has cracked oils at temperatures as low as 150-300°C. by using a catalyst composed of aluminum chloride, zinc chloride or magnesium chloride, mixed with bauxite. Marconi[72] has suggested the addition of oxidizing agents (manganese dioxide, lead chromate or copper oxide) to the combinations of various metallic halides, for instance boron trifluoride and aluminum chloride or antimony and aluminum chlorides, as a catalyst for cracking reactions. In a method introduced by Dubbs[73] streams of oil and an inert gas (e.g., carbon dioxide or flue gas) and aluminum chloride or nickel oxide are separately preheated, mixed and passed into a heated reactor. The pressure is increased in the latter step and thermolization is effected with the promoter suspended in the oil. Stratford[74] advocates employment of clay which has been utilized previously in the refining of lubricating oils.

Trumble and Seeley[75] propose to effect decomposition by means of a catalytic mixture of molten lead and nickel oxide. On the other hand, Cristescu and Stavrat[76] prefer alloys of two or more metals, for example, antimony, silver, chromium, tin and zinc, such that the specific heat of the metallic mix is less than 0.1. Alloys of lead and sodium (90 and 10 per cent respectively) are also said to be effective in their action.[77] Towne[78] recommends the use of molten selenium at 400-600°C. under pressures of about 300 lbs. per sq. in. in reforming gasoline. Tubes constructed of palladium-molybdenum-chromium-nickel alloys have been employed by Ocun[79] to promote decomposition. In this process, the stock is preheated to below the cracking temperature and vaporized under pressure in the presence of hydrogen. The vapors are then subjected to the action of superheated steam and rapid cracking at 1000-1500°F. and immediately allowed to expand and cool. Cracking may be brought about by heating heavy hydrocarbons to 350-550°C. under pres-

sure of 90 to 100 atmospheres in the presence of finely granulated metals and acids or chlorinated hydrocarbons capable of forming acids under the operating conditions.[80] Among the metals suggested are: vanadium, chromium, molybdenum, tungsten, manganese, nickel, iron, aluminum and zinc. Hydrochloric, sulphuric, nitric, phosphoric, and sulphonic acids, or acid salts are recommended for use in conjunction with the above metals, however, chloroform, bromoform, carbon tetrachloride and dichloroethane may also be employed. Moehrle[81] found that by heating hydrocarbons with about 1 per cent of iodine at 350° to 550°C. under 50 atmospheres pressure, cracking and polymerization of the olefins formed by the primary reactions could be brought about. A system involving progressive catalysis has been investigated.[82] In this method, the hydrocarbon vapors are mixed with steam and passed first over activated fuller's earth at 300-350°C., then over pumice stone impregnated with nickel, cobalt or copper at 300-450°C. and finally over activated fuller's earth mixed with nickel oxide, cobalt oxide or alumina at 150°

Ellis[85] recommends the use of catalysts such as molybdenum or tungsten oxides for cracking heavy petroleum oils containing sulphur compounds and simultaneously hydrogenating and methanating the products. In this procedure, the oil together with a gas mixture composed of hydrogen, methane and small amounts of carbon monoxide is heated to 480-550°C. under a pressure of about 50 atmospheres in the presence of the catalyst. The amount of hydrogen introduced should be insufficient to form a saturated liquid product under the reaction conditions. The liquid obtained from this treatment has been shown to have most of the original sulphur content removed as hydrogen sulphide. Egloff,[86] on the other hand, suggests the cracking of oils in the presence of finely divided alkali or alkaline earth hydrides (such as sodium hydride, NaH, or calcium hydride, CaH_2). This method is reported to hydrogenate the highly unsaturated hydrocarbons which are formed in cracking and to desulphurize the product. Hypochlorous acid vapor may also be used in vapor-phase processes to reduce the sulphur content of liquid products.[87]

The antiknock qualities of motor fuels are said to be improved by passing the gasoline vapors over phosphate catalysts at temperatures below the cracking range.[88] Granular boron phosphate (BPO_4), prepared by heating orthoboric acid with phosphoric acid on a steam bath has been suggested for this purpose. By passage over the contact agent at 450°C., the octane number of a straight run gasoline was reported to have been bettered from its initial value 55 to 62.5 without substantial loss due to the formation of gases.

COMMERCIAL CRACKING PROCESSES

The commercial processes employed in cracking may be divided into two general types, vapor and vapor-liquid phase operations. In the first type, the cracking reactions generally take place in the range of 500-600°C. (850-1150°F.) and at atmospheric or slightly super-atmospheric pressure, so that the hydrocarbons are in the vapor state. In the vapor-liquid or mixed phase type, treatment is carried out at lower temperatures, ordinarily 390-500°C. (750-850°F.), and under pressures of 200 to 1500 lbs. per sq. in. Formerly the latter type of processes was known as "liquid phase," but Sydnor[89] has stated that under the conditions employed, some of the hydrocarbons were undoubtedly vaporized so that a mixed phase system results. According to Sydnor, however, there are three reasons for maintaining the pressure operations: (1) the reduction of gas and coke formation, (2) better quality of distillate as regards ease of finishing and (3) higher capacity of apparatus secured in this case.

Developments in the design and operation of the various types of cracking plants have been influenced by a number of factors in addition to the increased

demand for high-octane gasoline. The aim of many of the improvements has been to increase the flexibility of operation, gasoline yields, length of runs, quality of tar (by reduction in coke formation) and to effect economies in fuel consumption. Developments of major importance include the use of multiple coil and combination units, the primary cracking of heavy residues to facilitate subsequent cracking and the reforming of gasolines[90] for the production of higher octane motor fuels.[91]

In multiple coil cracking, the charging stock is separated into two or more fractions each of which is cracked in separate units under conditions most favorable for efficient operation. In certain plants, distillation of crude oil, viscosity breaking (primary cracking), naphtha reforming and multiple coil cracking can all be carried out in one unit. Primary cracking consists in subjecting the heavy oil under treatment to an initial conversion per pass of 8 to 10 per cent. This operation results in the production of some gasoline as well as a large proportion of oil of a lower boiling point and lower molecular weight than the feed stock. The latter fraction may be cracked under relatively severe conditions, that is, at a high conversion per pass.

A complete discussion of cracking plants is beyond the scope of this volume. Only the principles and general procedure involved in the various processes will be briefly considered.[92]

---

Dubbs Process. A flow sheet of the Dubbs multiple coil unit,[93] one of the vapor-liquid phase type, is shown in Fig. 30. The crude oil as charged usually contains water as an emulsion which is separated from the oil in a settling tank. The crude oil is then passed to the crude fractionating column (about 7 feet in diameter and 47 feet high) from which straight-run gasoline, light oil (naphtha and kerosene) and heavy oil (topped crude) are obtained. The topped crude is pumped directly to a second column and is contacted with hot vapors from the cracking unit, causing a partial fractionation. The vapors from this column (10 feet in diameter and 58 feet high) are split into a liquid side cut which is pumped to a light oil heater and heated to 975°F. under 600 lbs. per sq. in. pressure and into an overhead consisting of vaporized gasoline and gas. The bottoms from this column are fed to a heavy oil preheater and heated to 910°F. at 300 lbs. per sq. in. pressure. Both heaters discharge to a reaction chamber under 300 lbs. per sq. in. pressure from which the material is fed into a flash chamber, where the pressure is reduced to about 75 lbs. per sq. in. The vapors from the top of the flash chamber are cooled and returned to the second fractionating column.

Tube and Tank Process. In the Tube and Tank process (also of the mixed phase type), the cracking reactions usually are carried out under high pressure (750-1000 lbs. per sq. in.). A flow sheet of a typical unit using this type of operation is given in Fig. 31. The fresh charging stock (normally gas oil) is preheated and introduced into a primary fractionating column, where it is contacted with cracked gasoline and cycle stock vapors. The cycle stock is condensed and

returned to the accumulator from which the fresh and cycle oil mixture (total feed) is pumped under pressure through the tubes of the heating furnace (maintained at 850° to 900°F.) and then into the reaction chamber where the bulk of the cracking takes place under a pressure of about 1000 lbs. per sq. in. The oil next flows to a separator, where the fuel oil portions are removed. The vapors from the separator are fed into the primary fractionating column under 100 lbs. per sq. in. pressure, where a portion of the cycle gas oil is removed. The vapors from this feed are now passed into a secondary column. The overhead from this treatment is conducted into a disengaging drum and the gas is separated from the gasoline.[94]

Cross Process. A flow sheet of the improved Cross process is shown in Fig. 32. In the earlier Cross method, the conversion per pass was too high to utilize residual oils as charging stocks. To overcome this limitation the manner of treatment was altered and primary cracking or viscosity breaking was employed. Further modifications have been introduced so that charging stocks varying from heavy fuel oil to the lightest kerosenes may be treated.[95] In the unit shown in Fig. 32 the straight-run gasoline is removed and reformed at 1000°F. and 750 lbs. per sq. in. The topped crude is split into two fractions, residuum oil and light gas oil. The former, together with the heavy recycle stock, are cracked in a primary chamber at 890°F. under a pressure of 250 lbs. per sq. in. The light gas oil, together with the light recycle stock, is cracked in the vapor phase at 940°F. and 200 lbs. per sq. in. pressure, using a furnace and reaction drum. The cracked gasoline is fractionated, condensed and separated from the waste gases while still under pressure.

Gyro Process. The Gyro process is an important vapor-phase unit which has been developed along the lines of Hall's general procedure.[96] Keith and Montgomery[97] have stated that an inherent inability of this process to handle residue stocks has been overcome by the provision for the predistillation of heavy charging stocks. This is accomplished by passing a heavy stock combined with recycle oil through a pipe still into a vaporizer. The vapors are freed from entrained liquid

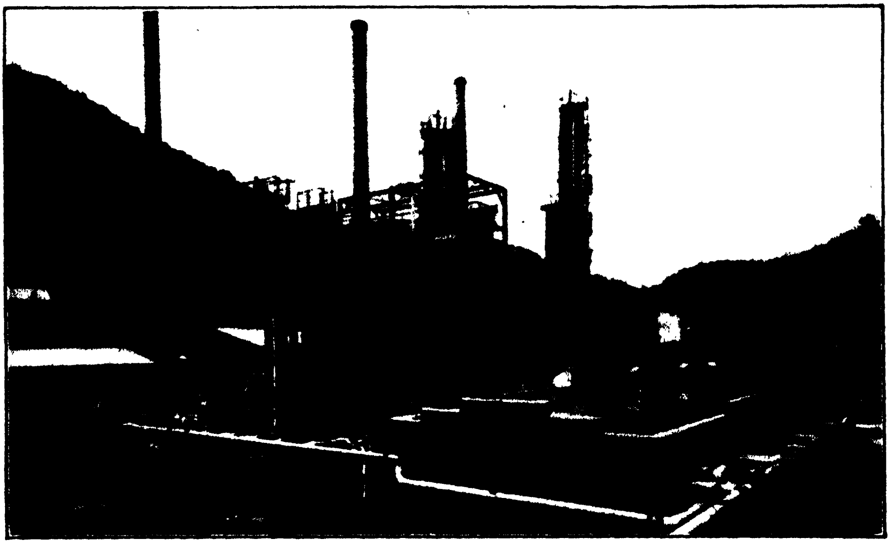
and fed into the cracking chamber where the temperature is rapidly raised to 1100°F. Immediately after leaving the chamber, the vapors are contacted with cooled recycle gas oil. The temperature is thus reduced to 700°F., and the effects of polymerization and over-cracking are greatly reduced or eliminated. A flow sheet of this process is shown in Fig. 33. The entire process operates at atmospheric pressure.

---

[96] The Hall process was introduced in 1914. See Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934, 164, for a discussion of this method.

[97] P. C. Keith and W. B. Montgomery, *loc. cit.* See also G. N. Critchley, *loc. cit.* K. Kudo. *J. Fuel Soc. Japan*, 1936, 15, 709; *Chem. Abs.*, 1936, 30, 6929, has described a Gyro vapor phase unit incorporating a thermal polymerization unit. (See Chapter 26 for a discussion of the latter topic.)

De Florez Process. The de Florez type of operation is applicable for the handling of feed stocks varying from kerosene to heavy pitches.[98] Fig. 35 is a flow diagram for a typical installation for cracking reduced crude oil. After preheating and passage through a tar stripper,[99] the stock is fed into an evaporator and vaporized at about 790°F. and 165 lbs. per sq. in. pressure. The lower-boiling portions enter the bubble tower, and the heavier fractions are fed into a reaction chamber (maintained at about 880°F. and 330 lbs. per sq. in.), where they are mixed with recycle material (bottoms from the bubble tower) which has been cracked by heating at 630°F. and 900 lbs. per sq. in. to 1000°F. and 350 lbs. per sq. in. in a furnace. Vapors from the reaction chamber are returned into the evaporator and the high-boiling liquid portions are recycled to the tar stripper. Bottoms from the stabilizer and absorber units are recirculated to the evaporator and bubble tower.



Courtesy Alco Products, Inc.

FIG. 34.—Gyro Process Cracking Equipment.

A de Florez cracking unit incorporating coking operation is represented in Fig. 36. In this case, the feed (reduced crude oil) enters the evaporator under 100 lbs. per sq. in. pressure. The lower-boiling portion (below 680°F.) is introduced into the bubble tower. The bottoms from the distillation column are heated in a furnace to 1010°F. under 300 lbs. per sq. in., mixed with the high-boiling residue from the evaporator and passed into a coking drum. Here at 880°F. and 250 lbs. per sq. in. with long periods of contact, the heavy residua are reduced to coke and vapors, the latter being returned to the evaporator. The coking drums are ordinarily about 40 feet high, and can be filled to a height of 30 or 35 feet with coke. Using two drums, to permit continuous operations, runs of as long as 3000 hours

---

[98] Discussions of the de Florez process have been given by J. H. Hirsch (*World Petroleum*, 1932, 3 (3), 335; *Chem. Abs.*, 1932, 26, 6109), and P. C. Keith and W. B. Montgomery (*loc. cit.*).

[99] The function of the tar stripper is to separate the light heads and heavy bottoms from the stock. The former are introduced directly into the bubble tower, as reflux, and the latter are removed as fuel oil.

Fig. 37.—Flow Sheet of True Vapor Phase Process.

T.V.P. Process. A description of the improved T.V.P. (True Vapor Phase) process has been given by Williams.[101] An important development in this method has been the replacement by tubular heaters of the "stoves" of the blast furnace type which were used formerly. The charge, ranging from heavy naphthas to heavy reduced crudes, is preheated by means of scrubber vapors, passed into a vaporizer (heated to 800-825°F.) and then into a flash drum, where vaporization is effected by means of hot gas. The vapors are then fed into a superheater coil where the temperature is raised to 1000°F. and finally enter the reaction chamber. Cycle gases (heated to 1150°F.) are introduced into the flash drum, superheater or reaction chamber feed, so that the actual reaction temperature is about 1020°F. The cycle gas heater, vaporizer and superheater coils are all incorporated into a single convection-type gas-fired furnace as indicated in the flow sheet for this process, given in Fig. 37. The vapors from the reaction chamber are scrubbed, bottoms removed, and condensed. The overhead gases are returned as recycle feed. This treatment is said to give little or no coke or carbon.

Forward Process. A description of the Forward Process has been given by Kaplan and Forney.[102] In this unit, distillate oil is preheated to 900°F. and passed through a cracking coil (1 inch in diameter and about 2300 feet long), maintained at 1050°F. under a pressure of 225 lbs. per sq. in. The velocity of the gas is arrested in a carbon settling chamber (also kept at 1050-1075°F.). The cracked vapors leaving the top of the chamber are quickly chilled by means of a water spray, condensed and fractionated. Fig. 38 represents a flow diagram for this type of operation. The aromatic content of the gasoline obtained from gas oil charging stock with this method is reported as being about 85 per cent.

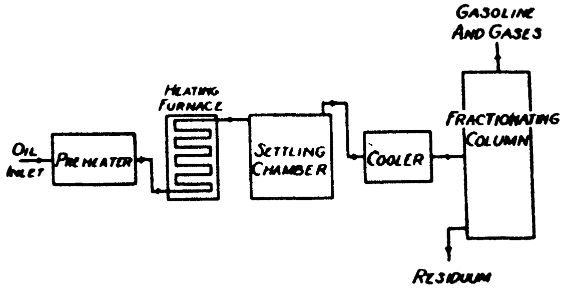

Fig. 38.—Flow Diagram of Forward Vapor Phase Process. (Described by W. Kaplan and W. E. Forney)

Shukhov-Kapelyushnikov Process. The Shukhov-Kapelyushnikov cracking unit is reported to be one of a vapor-phase type in use in U.S.S.R.[103] In this method, gas oil under 15 to 16 atmospheres pressure is forced into a furnace and heated sufficiently so that the temperature in the reaction chamber into which the material is next fed will be 570-580°C. In the latter apparatus the pressure is reduced to 1.5 to 3 atmospheres. The yield of 210°C. end point gasoline is given as 38 to 40 per cent. The refined product is stated to be highly aromatic in character.

Dubrovai Process. In the Dubrovai vapor-phase cracking unit (a flow sheet of which is given in Fig. 41), the stock is preheated to about 400°C. in a tube still and passed into a "generator." In this chamber the temperature of the stock is raised to 500°C. and air is introduced. Cracking takes place and the vapors are fed into a flashing tower, fractionated and condensed. The process operates at atmospheric pressure. In the so-called generator, the cracking temperature is probably considerably lower than is customary with other vapor-phase cracking units, according to Dubrovai and Sheinman.[104] The principal product of combustion is water and only insignificant amounts of carbon monoxide and carbon dioxide are reported to be formed. Carbon is deposited in the generator, however, and is periodically burned out with air. The amount of air used in the cracking process varies from 180 to 240 liters per kilogram of cracking stock, depending upon the preheating temperature and the nature of the feed stock.

Clark Process. This vapor-phase process[105] differs from others in that cracking is effected by directly mixing hot products of combustion with superheated oil vapors, rather than by indirect heating, as through steel tubes or other metallic surfaces.[106] In Fig. 42, is a flow sheet for this method. The crude oil is preheated and fed into a fractionating column, from which a gas oil cut is taken off. Part is reintroduced into the tower as controller reflux, and the remainder is pumped directly to a two-stage heater. Here the stock is vaporized at 750°F., passed into a flash drum (to remove unvaporized portions), and the vapors returned to the furnace for superheating to 810°F. The superheated gas oil vapors are now contacted with hot combustion gases at about 1010°F. in a constricted connection between the combustion chamber and the reactor, for a period sufficient to permit cracking to gasoline, without over-cracking and the attendant large gas loss. In the combustion chamber (usually horizontal), heat is produced by burning refinery or stripped gas, pipe line gas, or fuel oil, with the amount of air necessary for complete combustion, under a gage pressure of about 40 lbs. per sq. in. (It is necessary to properly proportion the amounts of fuel and air so as to give a non-coking flame containing no excess oxygen.) The combustion vapors must be oxygen-free or partial oxidation of the charge would occur. After passage through the reactor, the gases are introduced into the fractionating column. The overhead from the column consists of fixed gases and gasoline, which are separated. The bottoms are said to be adaptable as a highway construction material.

Houdry Process. The so-called "Houdry Process" is based upon the vapor-phase cracking of crude oils in the presence of a catalyst and was introduced in this country in the latter part of 1930 after being developed in France to some extent.

---

[105] L. Clark, U. S. P. 1,491,518, Apr. 22, 1924; *J.S.C.I.*, 1924, **43**, 460B. British P. 132,377, 1918; *J.S.C.I.*, 1919, **38**, 809A U. S. P. 1,989,455, Jan. 29, 1935; *J. Inst. Pet. Tech.*, 1935, **21**, 135A; *Chem. Abs.*, 1935, **29**, 1975; *Brit. Chem. Abs.* B, 1935, 1035.

[106] A description of this process has been given by J. C. Albright, *Refiner*, 1935, **14**, 43; *J. Inst. Pet. Tech.*, 1935, **21**, 168A; *Chem. Abs.*, 1935, **29**, 2712.

The advantages of the method of treatment involved in this procedure are said to be in the use of moderate temperatures and pressures and in the formation of a high octane gasoline (75 to 85 octane number, depending upon the charging stock) and a residuum of the gas-oil boiling range. The latter is reported to be applicable as a Diesel fuel or a domestic fuel oil. The untreated gasoline is stated to possess low gum and sulphur contents and high oxygen-bomb stability. The production of gasoline in the Houdry Process is held to be the result solely of catalytic action. This assumption is also evidenced by the products, gasoline, residual oil and gas, which have been found to be quite different in their molecular structure from the corresponding resultants of other processes.[107]

In general, the process is adaptable to a wide range of petroleum distillates which vaporize in the neighborhood of 775° to 875°F. and may be employed in either of two ways. The charging stock may be cracked to a yield of about the same as or slightly higher than that of mixed phase thermal treatments, or it may be run to a 35 to 50 per cent conversion (depending upon the stock) and the residual oil cracked in a separate thermal plant. A catalyst of high activity is used. However, since the catalytic action of the contact mass is greatly lowered due to the deposition of carbonaceous material, a regeneration process is necessary. Each of these factors will now be discussed in more detail.

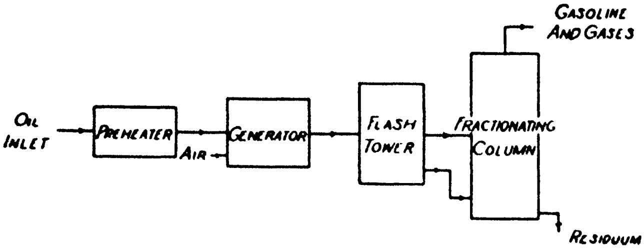

FIG. 41.—Flow Diagram for Vapor Phase Cracking Using Air. (Described by K. K. Dubrovai and A. B. Sheinman)

The Houdry plant embodies standard refinery equipment, except that catalysts cases and a regenerating system must be included.[108] The only important difference is that the catalyst cases are substituted for the reaction chambers. A flow sheet of this type of operation is shown in Fig. 43. Petroleum oil is preheated, mixed with a small quantity of steam and vaporized in the temperature range of 775 to 875°F. and at substantially atmospheric pressure.[109] Joseph[110] has stated that up to 15 per cent of steam may be incorporated with the oils. However, 5 per cent is recommended, as the presence of too large an excess of steam is objectionable, especially in the subsequent distillation of the reaction mixture. (According to Joseph, the steam is not decomposed in this stage and assists only in vaporizing the oil.) The mixture of oil vapor and steam is passed over solid molded catalysts which are contained in cylindrical steel cases, provided with a system for regenerating the catalyst. The product is fed into a fractionating column and the recycle oil removed. Gasoline, fixed gases and steam are cooled and separated and the gasoline recovered from the fixed gases by the conventional methods.

FIG. 42.—Diagrammatic Sketch of Clark Vapor Phase Cracking Process.

As mentioned previously, the activity of the catalyst is greatly decreased by the deposition of carbonaceous material. Therefore, the contact masses can be used for only a limited period of time before the stream of oil vapor and steam is switched to another catalytic chamber. This may be accomplished quite readily by manipulation of the valves as represented in Fig. 43. The regeneration process consists of two steps. The fouled catalyst is first steamed to remove oil vapor and is then regenerated by blowing through it a mixture of air and the products of combustion from other catalyst cases. The regenerating medium enters the chambers at 150°F. and leaves at 1000°F. These temperatures are said to effect complete elimination of sulphur and carbonaceous material and still be well below those at which the contact agent would be depreciated in activity. Continuous operation is secured by providing several catalysts cases, so that some are always "on stream" (in actual operation) while others are being reactivated.

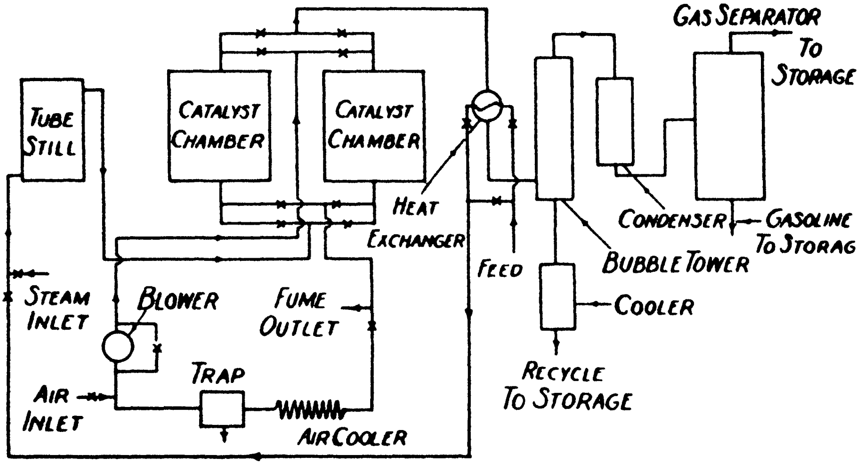
[109] Cracking must be limited during the vaporization to the extent usually effected in good topping-still operation.

[110] A. Joseph, U. S. P. 2,000,960, May 14, 1935, to Houdry Process Corp.; *Chem. Abs.*, 1935, **29**, 4569; *J. Inst. Pet. Tech.*, 1935, **21**, 270A.

Joseph[111] advocated regeneration by means of a mixture of air or oxygen and steam. Under the conditions generally used, dissociation of the steam gives rise to the formation of oxygen and hydrogen. The oxygen thus set free adds itself to that of the injected air, aiding in burning the carbon to carbon monoxide and carbon dioxide and the sulphur to sulphur dioxide. The nascent hydrogen reduces the sulphur dioxide to hydrogen sulphide and likewise reduces metallic sulphides which might have been formed in the catalytic material.

The catalyst used in the Houdry process must be capable of withstanding the repeated regeneration operations necessary. The contact material generally employed is of the clay type (either natural or synthetic) and is characterized by a high content of silica and alumina, generally in a weight ratio of about 3½ or 4 to 1.



Courtesy Oil and Gas Journal

FIG. 43.—Schematic Representation of Houdry Process.

The clay should contain not more than 10 per cent of iron, calcium and magnesium oxides, and particularly not more than 3 per cent of iron oxide. (The latter substance is thought to have a critical relation to the regenerative operations.) A material which was said to be very satisfactory had the following composition: silica, 76 per cent, alumina, 16.8 per cent, iron oxide, 1.6 per cent, calcium oxide, 2.4 per cent, and magnesium oxide, 1.3 per cent. In making the catalyst, the material is broken up into small fragments, activated by acid treatment, moistened with water or oil, and then molded into a pellet and baked. Promoters, such as nickel, cobalt, copper, manganese, vanadium and molybdenum, may be mixed with the clay prior to the moistening and molding operations.[112]

The preparation of a synthetic contact mass consisting of activated aluminum silicate and a plastic silicate, such as clay, is described by Joseph.[118] Thus, 85 parts of activated aluminum silicate and 12 parts of argillaceous silicate of aluminum are slaked in cold water. Three per cent of alumina (obtained by the action of sodium hydroxide on aluminum sulphate) are added and the resulting material molded into annular pellets (7 to 8 mm. external diameter, 2.5 to 3 mm. internal diameter and 10 to 20 mm. in height) and dried.

Houdry[114] has proposed a system of progressive catalytic treatments to effect simultaneous cracking and refining of oils. The oil is vaporized, with steam, and the vapors passed over adsorbent silicates at 550° to 1000°F. In a second chamber, the material is contacted with earthenware fragments (impregnated with nickel or cobalt oxides) at a temperature of 600-800°F. The final operation is carried out at 300-600°F. using an adsorptive silicate impregnated with nickel or cobalt.

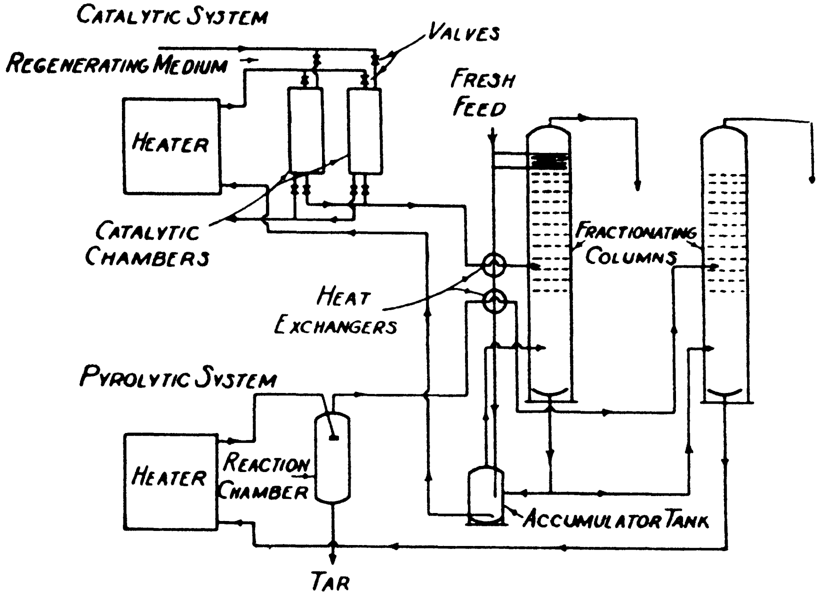

Fig. 44.—Cracking Method Employing Both Catalytic and Thermal Units. (J. P. Daugherty, Jr.)

The residual oils from the Houdry treatment are best cracked in a special unit under separate operations, since successive recycles require differing conditions for best results. These residues have been found to be good feed stocks for thermal units, and so Daugherty[115] has suggested the incorporation of two units, the first of the catalytic type and the second thermal, as shown in Fig. 44. The crude oil is first cracked by the Houdry method and the reaction mixture fractionated in the first column to remove the gasoline portion. The bottoms from this fractionating tower are passed into a second tower (part of the residuum may be diverted into recycle stock for the catalytic system) and then into the heater of the pyrolytic unit, which may be any one of the several types mentioned previously in this chapter. The vapors from the reaction chamber are fed into the second fractionator where additional quantities of gasoline are removed. In this manner, the advantages of both systems may be utilized.[116]

Other Processes. Efforts to increase the quality and yield of the motor fuel produced by cracking have resulted in a number of variations on the procedures mentioned above. Lederer[117] has described the Heckmann process, in which the cracking operation is divided into three stages of sucessively higher, lower and intermediate temperature. In each unit, after the separation of the gasoline and asphalt the middle oil is recirculated. Giordani[118] has discussed the Carburol process which is held to be especially adapted to the production of asphalts as well as gasolines from heavy stocks. In this method, the oil is kept in the cracking zone for 1 to 2 minutes, and secondary reactions are eliminated by sudden cooling. Smith[119] has suggested a two-stage cracking mechanism in which the vapors from liquid-phase operations are subjected to vapor-phase reforming. Likewise the feed stock may be cracked in the vapor phase at 540-675°C. and low pressure. The vapors from this stage are cooled by contact with fresh charging stock, and the latter mixture is fractionated to remove gasoline and fuel oil portions. The residual oil is then subjected to liquid-phase cracking.[120] Holding the cracked oil at a temperature slightly below that used in the cracking operation while still maintaining the high pressure (in order to allow polymerization of the gum forming substances) has also been proposed.[121] Cracking in the presence of recycled gaseous olefins has been stated by Sullivan[122] to improve the quality of the motor fuel. Dilution of the vapor with an inert gas such as nitrogen has been suggested.[123]

Processes involving cracking by means of molten metal as the heating medium have also been proposed. Slowter, Hobart and Withrow[124] have stated that neither tin nor lead has any catalytic effect when compared to ordinary steel heat-transfer surfaces. However, these investigators found that the use of molten metal baths resulted in better heat transfer, more uniformity in temperature control, and a minimizing of coking on the heat-transfer surfaces. According to Garofalo,[125] oils may be cracked in the vapor phase by injecting the hydrocarbon vapors into molten lead.[126] Govers[127] suggests the elimination of secondary cracking reactions by preheating the oil to 400°C. and contacting it with molten lead at 540°C. The

[116] The exhaust gases from the cracking operation may be catalytically polymerized to form gasoline in units similar to those mentioned here. Suggestions for this procedure have been given by E. J. converted oil is immediately removed from the reaction zone and cooled. The cracking reactions are said to occur instantaneously.[128]

Electrical cracking has also been investigated. Fischer, Peters and Winzer[129] have studied the effect of a high tension electric arc on liquid hydrocarbons. The yield of gases was about 4 times that of liquids. Hydrogen was the predominant gaseous product, with acetylene the principal unsaturated constituent. Peters and Winzer[130] have discussed the cracking of Kogasin II[131] using platinum wire and graphite rod electrodes. The data from these tests are incorporated in Table 32.

TABLE 32.—*Cracking of Kogasin II with Graphite and Platinum Electrodes.*

	Graphite Rod	Platinum Wire
Current, amps	14	36
Power, watts	112	730
Duration of test, min.	108	58
Productivity, g./k.w.h.	143.5	295.0
Products, weight %		
Gas	85.3	84.4
Liquid	14.7	15.6
Composition of cracked Gas, volume %		
Unsaturates	69.0	71.6
Hydrogen	12.7	12.1
Saturates	18.3	16.3

The products in each instance are quite similar, and consist mostly of unsaturated gases. Both electrodes became coated with a tight, glossy, thin layer of carbon, and it was thought that the actual decomposition of the hydrocarbons took place on this incandescent graphitic surface and not on the electrode itself. Gobert[132] has obtained 35 to 40 per cent yields of acetylene by cracking heavy oils in an electric arc. Hydrogen, ethylene and small amounts of methane and nitrogen were also formed. The production of 1 cubic meter of gas (containing 40 per cent acetylene) from 800 g. of oil required an energy input of 3.5 kilowatt hours. High boiling tars and oils may be cracked by heating to 200 to 500°C. under 2 to 50 atmospheres pressure when subjected to the influence of high frequency fields.[133] Low frequency currents may also be used for this purpose.[134]

AQUOLIZATION

Aquolization is a process in which hydrocarbon oils are cracked in the vapor phase in the presence of large excesses of steam. Most procedures involving this method of treatment call for ratios of about 18 to 80 moles of water to 1 mole of oil. Using this procedure, polymerization is said to be negligible and, furthermore, there is substantially no coke or tar formation. However, small amounts of water do react with the hydrocarbons to yield aldehydes, alcohols, ketones, acids, and carbon dioxide. The temperature range for aquolysis is from 900 to 1300°F. and the pressure limits usually from 70 to 1000 atmospheres. Ordinarily, pressures in the magnitude of 200 atmospheres are used. The time of contact varies from 0.1 to 2 minutes, depending upon the other factors. The charging stock may be crude oil, fuel oil, gas oil, tars and tarry oils, shale oils and oil emulsions. It is desirable, however, that the water used should be soft in order that mineral matter will not be deposited in the apparatus.

Ellis[135] has described one procedure (See Fig. 45) in which water and gas oil are forced under a pressure of 3000-3500 lbs. per sq. in. through a heat interchanger and a preheater and into the reaction chamber. In this unit, the reaction mixture is kept at 1000° F. for 20 seconds. The vapors leaving the reaction zone are cooled slightly below the critical temperature (400-500° F.) so that water separates as a liquid phase. Without reduction in pressure, the converted oil is removed from the water, and the latter is recirculated. The product is distilled and subsequently refined. Conversions as high as 75 per cent to motor fuel (boiling below 430-450° F.) have been obtained with this procedure using 4 parts of water to 1 of gas oil. Ammonia may be substituted for water in this process. Haslam[136] has suggested introducing superheated steam into vaporized gas oil and recycling the fixed gases in the system. He also mentions the use of catalysts such as iodine, ferric chloride or the oxides of nitrogen, although this variation is generally unnecessary since the reaction velocity is ordinarily quite fast. According to Haslam, operations carried out at 1200° F. under 3000 lbs. per sq. in. pressure with a reaction time of 13.4 seconds using a mixture of 18 moles of steam to 1 mole of oil resulted in a yield of 72 per cent of high antiknock gasoline. The residue obtained from the treatment was not a heavy tarry mass, as is the usual case in pyrolytic cracking operations, but was very similar to the original gas oil in its appearance.

[136] R. T. Haslam, U. S. P. 1,956,573, May 1, 1934, to Standard Oil Development Co.; *Brit. Chem. Abs.* B, 1935, 216; *Chem. Abs.*, 1934, 28, 4215; *J. Inst. Pet. Tech.*, 1934, 20, 463A.

White[137] has investigated the aquolysis of emulsions of both oil-in-water and water-in-oil types. He reports a 92.8 per cent conversion of gas oil to motor fuel boiling below 435°F. by treating an emulsion containing 80 moles of water to 1 mole of gasoline. The exemplified conditions for the aquolization were 1000°F. and 3000 lbs. per sq. in. pressure with a contact time of 65 seconds.

Several variations on the aquolization principle have been proposed. Foss[138] has suggested vaporizing hydrocarbons under pressure and feeding in steam heated to 1200°C. The operations are carried out in a series of tubes which are provided with traps to discharge both liquid and gaseous products. Egloff[139] prefers to add a solution of magnesium chloride to the oil prior to the heating and reaction zones. The magnesium chloride decomposes, forming magnesium hydroxide and hydrochloric acid. By this treatment, the sulphur content of the product is said to be reduced, and at the same time a partial hydrogenation and chlorination of the unstable unsaturated compounds are effected.

Russell[140] advocates agitating oil, water and a gas rich in carbon dioxide to form an emulsion. On contacting this mixture with waste gaseous products of combustion, the oil is cracked. By agitating oxygen with the mixture of oil and water and spraying the emulsion into a heated retort, cracking and partial combustion occur.[141] The resulting vapors are subsequently hydrogenated to form gasoline.

MATERIALS AVAILABLE FOR CONSTRUCTION OF CRACKING EQUIPMENT

The question of materials for the construction of the various parts of cracking units has been discussed by Morrell, Mekler and Egloff.[142] These authorities have pointed out that alloy steels have been in increasing demand in the cracking industry because of the higher operating temperatures now prevalent. To be satisfactory for use in these operations an alloy must possess three major properties: (1) resistance to corrosion of surfaces in contact with the hot oils or vapors undergoing treatment, (2) stability and strength at high temperatures and pressures and (3) resistance to oxidation and the oxides of sulphur on the surfaces directly exposed to combustion gases.

Formerly, stainless steels were employed in handling highly corrosive crudes. However, due to the crystallizing tendency of chromium under high temperatures, these steels become very brittle and therefore unsafe after protracted use. Chromium-nickel steels were next substituted. The stability of the latter type of alloys with regard to heating and cooling has been greatly improved by the addition of small percentages of carbon and molybdenum. Schiffler[143] reported that alloying these steels with 0.05 per cent of molybdenum, 0.1 per cent of vanadium or 0.6 to 0.8 per cent of aluminum improves the heat-resistance properties.

According to Morrell, Mekler and Egloff, the resistance of alloys to oxidation is determined by the chromium content of the steel. Thus, the higher the percentage of chromium, the lower the amount of oxidation that will take place. However, the economical angle must also be considered so that, in general, low chromium pearlite steels (containing 4 to 6 per cent of chromium) to which molybdenum and titanium have been added to give mechanical stability and strength have found application. Dixon[144] has suggested mixing about 2 per cent of silicon with these steels especially for use with corrosive stocks such as sulphur-containing oils. Chromium steels containing less than 2 per cent nickel have also been employed.[145]

Coating the steels with aluminum (or calorizing, as it is commonly called) has been used extensively to prevent corrosion and oxidation of metallic surfaces. The calorizing coating of aluminum is quite thin (in the magnitude of 0.005 inch ordinarily), so that mechanical cleaning of parts protected in this manner must be avoided. Winkler and Feiler have suggested burning silicon or titanium into the metal as one method of reducing surface corrosion.[146] Likewise, the V2A series of steel alloys (17 to 19 per cent chromium and 8 to 9 per cent nickel) coated with molybdenum have also been reported as effective in withstanding surface action.[147]

Schiffler has recommended the use of nickel-free steels for high pressure units. These alloys contain 8 per cent of chromium and up to 4 per cent of aluminum and 2.5 per cent of copper.[148]

CRACKING OF HEAVY HYDROCARBON FRACTIONS

Numerous investigations have been conducted with the view of obtaining motor fuels and other products of utility from tars and waste materials.[149] Armistead and Ullrich[150] have suggested converting sludge oil into gasoline. In their method the heavy oil is washed with strong sulphuric acid to form a sludge, which is then mixed with water and gas oil in the ratio of 3:1:2, respectively. Live steam is introduced into the mixture to facilitate the separation of the oil and aqueous layers. After settling, the hydrocarbon portion is removed and the diluent oil recovered by distillation. The distillation residue is then subjected to high pressure cracking at about 400°C. to produce motor fuel.

Oils containing large quantities of sulphur may be treated to eliminate the greater part of this element prior to cracking. Stratford[151] has proposed to refine materials such as a high sulphur-content gas oil or reduced crude oil of paraffin base by solvent action. Thus, extraction of the oil with phenol was found to remove most of the sulphur. The gasoline obtained by cracking oil purified in this manner is said to be of very low sulphur content and may be refined readily by means of solid adsorptive catalysts of the clay type.[152] Pelzer prefers to disperse a desulphurizing agent such as lime or copper oxide in the crude oil and subject the mixture to distillation under pressure.[153]

The cracking of sapropelite tar at 454°C. and 52 atmospheres pressure is reported to give a gasoline with an initial boiling point of 35 to 40°C.[154] The paraffinic fractions of peat tars have been found to give a yield of 30 to 33 per cent motor fuel in a single vapor-phase cracking operation.[155] Coal tars have been cracked using both vapor-[156] and mixed-phase[157] operations. although, in the latter case, according to Rapoport and Kaftanov,[158] the high yield of coke (about 40 per cent) from certain types of coal tars is objectionable. Gasoline, kerosene and coke are recovered from these tars.[159] The cracking of coking still distillates,[160] shale

oil,[161] residuum tar,[162] waste rubber[163] and lignite[164] have also been investigated as sources of motor fuels.

The production of motor fuels by the vapor-phase and catalytic cracking of vegetable oils was studied by Koo and Cheng.[165] Vapor-phase cracking of rapeseed oil at 1000°F. yielded 70 per cent of a crude oil, of which 40 per cent boiled below 200°C. Soybean oil, cottonseed oil and China wood oil (tung oil) gave analogous results. Using sodium hydroxide as a catalyst, at 800°F. rapeseed oil formed about 56 per cent of a crude oil, slightly more than half of which boiled in the gasoline range. A kerosene fraction may also be obtained from the crude oil, and by mixing the crude with the vegetable oil, fuel oils stated to be of the Diesel type result.

CRACKING OF MISCELLANEOUS STOCKS

As has been mentioned previously, although the formation of gasoline from higher boiling oils is the chief aim of cracking processes, it is not the only end to which this type of operation may be extended. Numerous applications of the cracking reaction with respect to stocks other than those ordinarily employed will be considered here.

Pyrolysis of a cracking gas (containing 48.6 to 66.7 per cent by weight of reactive hydrocarbons) freed of gasoline fractions has been investigated by Pletnev.[166] By cracking at 5 atmospheres pressure and 625°C. the reactive hydrocarbon content of the exit gas was reduced to 21.2 per cent and at higher temperatures (680°C.) to as low as 1.5 per cent (by weight). Best results were obtained at 660°C. yielding a motor fuel with an octane number of 99.

Kanep[167] studied the cracking of aviation gasoline (boiling range 65° to 100°C.) freed from pentanes, a naphtha fraction (naphthene base, b.p. 95° to 110°C.) and cyclohexane at temperatures of 650°, 700° and 750°C. The gases obtained by cracking the gasoline and cyclohexane at 700°C. contained 4.5 and 7.4 per cent butadiene, respectively. Ethylene, propene, benzene and toluene were formed in the pyrolysis of the gasoline and the naphtha fraction. However, with cyclohexane both propene and toluene were absent from the reaction products. Kanep attributes the high yields of ethylene (20 per cent) observed in the decomposition of the gasoline to the rupture of 5-membered rings.

Candea and Kühn[168] found that by cracking a gasoline fraction (distilling between 35° and 150°C.) at 600°C. a yield of 52 per cent of gas and practically no liquid resulted. By thermally decomposing this material at slightly lower temperatures (550°C.), the olefinic content of the liquid was increased from 7 per cent to 36.5 per cent and the aromatics from 10 to 15.5 per cent. Likewise, cracking kerosene at 650°C. caused the olefinic constituents to increase from 6 per cent to 40 per cent, while the percentage of aromatics in the liquid increased from 14.5 to 20.5. However, under the latter conditions 71 per cent of the kerosene decomposed to gases. At higher temperatures with long periods of contact and catalysts (such as a mixture of nickel, iron, manganese and calcium oxides) these investigators show that complete dissociation to carbon and hydrogen may result. The catalytic cracking of Rumanian kerosene (b.p. 150-300°C.), containing 16 per cent aromatics, 5 per cent unsaturates and 79 per cent paraffins and naphthenes, was investigated by Candea and Sauciuc.[169] In the temperature range of 450-770°C. the maximum yield (49 per cent) of low-boiling hydrocarbons was obtained, using activated carbon as catalyst. With increasing conversions to the lower hydrocarbons, the proportions of olefins and aromatics in the liquid formed also rose. Aluminum silicate especially promoted the production of highly aromatic liquids. Metallic catalysts, such as nickel, however, increased the formation of gases. Kanep[170] has pyrolyzed various kerosene fractions at 700°C. His results indicate that the aromatic content of the cracked liquid decreases with the increased boiling range of the fraction. Thus, the percentage of aromatics produced by cracking the various fractions at 700°C. are:

Fraction	Aromatics
Below 150°C.	20.9%
150-210°C.	15.6%
210-270°C.	12%
270-300°C.	12%

In the first of these fractions (that boiling below 150°C.), the quantity of benzene formed was greater than that of toluene; however, this condition was reversed in the other fractions. According to Kanep, the yields of aromatics obtained in the cracking of kerosene distillates are dependent upon the type, the lighter kerosenes giving the highest conversion.

Experiments on the pyrolysis of cylinder oil (sp.gr. 0.92) have also been conducted by Kanep.[171] Although the oil was relatively stable at low temperatures, at 600°C. it yielded 83 per cent of vapors. Decomposition was mainly into hydrogen, methane and carbon, with but small quantities of olefins. The yield of butadiene at 650°C. was only 2.5 per cent. Benzene and toluene were produced in about the same molar ratio. However this is attributed to the highly cyclic nature of the oil.

D'yakova and Petrov[172] have investigated the thermal stability of a number of the higher naphthenes in cracking processes. Synthetic decalin, bicyclohexyl, methylisopropylbicyclononane and amylcyclohexane were cracked under ordinary pressure in an atmosphere of nitrogen. Naphthenes, isolated from Grozny non-paraffin oil and from products of olefins cracked under pressure, boiling within the same ranges as the above-mentioned cyclic compounds, were also cracked under the same conditions. From the yield and nature of both the liquids and gases obtained in these treatments, D'yakova and Petrov believe that the naphthenes of the Grozny oil are more closely related to the monocyclic naphthenes with a long side chain rather than to the bicyclic naphthenes of the type of decalin and bicyclohexyl.

The cracking of Grozny paraffin (m.p. 53.2°C.) has been studied by Katzman.[173] This material was fairly stable at 600-640°C., only small amounts of benzene (C_6H_6) being formed. At 650°C., however, more than 65 per cent of the paraffin was converted into gases (principally ethylene and propene). In addition, a 2.5 per cent yield of butadiene and a large yield of benzene but only a small amount of high boiling fractions were obtained under these conditions. The effect of the pressure of different gases on the cracking of solid paraffin wax has been noted by Weinstein.[174] At 440°C. under a pressure of 70 to 80 kg. per sq. cm. of nitrogen, the cracking of high molecular weight saturated hydrocarbons resembles closely the analogous reaction carried out with the same substances under reduced pressure. When hydrogen is substituted for nitrogen under the same conditions of temperature and pressure, much less decomposition occurs as is evidenced by the gases evolved and the quantity of liquid boiling below 230°C. Weinstein concludes that the effect of hydrogen is specific and is not common to gases which in general are classed as inert. The effect of the pressure of hydrogen on the production of cyclic compounds in cracking Rangoon paraffin wax at high temperatures has been discussed by Waterman, Leendertse, Adam and van Vlodrop.[175] When the paraffin was cracked thermally, in the absence of hydrogen, the average number of rings produced per mole of wax was 1.6 to 1.7. Under high pressure of hydrogen, however, the average number of rings formed per molecule of wax decomposed was reduced to only 0.4 to 0.5. Using hydrogen in the presence of nickel or kieselguhr, the ring formation was completely prevented.[176]

PRODUCTS OF COMMERCIAL CRACKING PROCESSES

The products obtained in commercial cracking processes may broadly be classified as gases, liquids and coke. Both the quantity and composition of all three of these substances vary considerably, depending not only upon the operating conditions of temperature, pressure and heating time, but also upon the charging stock and type of plant. Because of the enormous scale upon which cracking is conducted and, furthermore, because of the increasing demand for higher quality gasoline, a knowledge of the composition of the hydrocarbons formed in the cracking reactions is very important. Unfortunately, because of the complexity of the problem of determining the almost innumerable constituents of these resultants, complete information is not on hand. However, from the general trend of the data available, the composition of these cracked petroleum hydrocarbons may be roughly indicated.[177]

COMPOSITION OF CRACKED GASES

The factors determining the amount and composition of gases formed in cracking are the four fundamental variables;- temperature, pressure, time and composition of feed stock. Egloff and Morrell[178] have studied the cracking of various oils in the commercial production of gasoline from the viewpoint of gas formation and gas composition. Their tests were made using a vapor-liquid phase system with operating conditions of 250 to 750 lbs. per sq. in. pressure and temperatures ranging from 875-975°F. (468-524°C.). The feed stocks included Midcontinent gasoline, naphtha and kerosene, California kerosene, mixed heavy naphtha and light gas oil and gas oil, Coastal and East Texas gas oils, Midcontinent and Somerset topped crudes and Mt. Pleasant and Refugio crude oils. The resultants in these cracking operations were gasoline (from 52 to 76.8 per cent of the charge), flashed liquid residue (up to 47.1 per cent of charge), and gas (from 164 to 1182 cu. ft. per barrel of oil). In the case of the Somerset topped crude, however, the cracking was allowed to go to gasoline, gas and coke. The conditions of these tests, yields and gas analysis are included in Table 33. In every one of these tests, it will be noted that methane and other uncondensable gases formed the bulk of the gas. The other principal constituents in the descending order of amounts produced are ethane, propene, propane and ethylene. The quantity of acetylene obtained is quite small.

---

[177] See Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[178] G. Egloff and J. C. Morrell, *Ind. Eng. Chem.*, 1934, 26, 940; *Chem. Abs.*, 1934, 28, 6988; *Brit. Chem. Abs.* B, 1934, 1044; *J. Inst. Pet. Tech.*, 1934, 20, 527A.

Markovich[179] has correlated data on the composition of the gases obtained in vapor-liquid and vapor-phase cracking as well as cracked gases from petroleum stills. Although the composition of the exit gases varies greatly with the operating conditions (especially in mixed-phase processes), Markovich states that these average values (as given in Table 34) are fairly representative. Thus the differentiation he makes between vapor-phase and mixed-phase cracked gases is that the former are of high olefinic content (about 45 per cent) whereas the latter are practically paraffinic (about 72 per cent total saturated hydrocarbons). The nature of the cracked gas from the distillation operations and that from vapor-phase cracking are quite similar.

TABLE 34.—*Average Composition of Cracked Gases.*

	Liquid-Vapor Phase	Vapor Phase	Still
Hydrogen	3	9	12
Methane	50	28	56
Ethane	17	14	
Propane	10	3	
Butane	5	1	
Higher paraffins	—	—	0.4

Propene	9	15	9.0
Butene	4	5	1.6
Isobutene	—	3.5	2.4
Butadiene	—	1.5	1.6
Higher olefins	—	—	1.2

Vapor-phase cracking with specific reference to the gases formed has also been investigated by Otsuka.[180] His experiments were carried out with gas oil at temperatures of 550-750°C. and pressures of about 720 mm. At 550°C., neither hydrogen nor methane was produced, however as the temperature was increased, the formation of hydrogen increased at a fairly rapid rate while that of methane increased very rapidly. Ethane, propane, ethylene and propene and smaller amounts of *n*- and isobutene were present in the gas formed at low temperatures. The maximum value of the C_4 fraction (mainly butenes) was obtained by cracking at 600°C., at which temperature the ethylene formation was a minimum.

NATURE OF LIQUID PRODUCTS OF CRACKING REACTIONS

As might be expected, the composition of the liquid products also varies greatly with the conditions of cracking. Thus, Otsuka[181] has shown that in vapor-phase cracking in the range of 550-700°C. (1020-1290°F.), the sum of the weight percentages of aromatic and olefinic hydrocarbons remains almost constant. At 750°C., however, dehydrogenation of the naphthenes and decomposition of the paraffins to form aromatics become predominant.

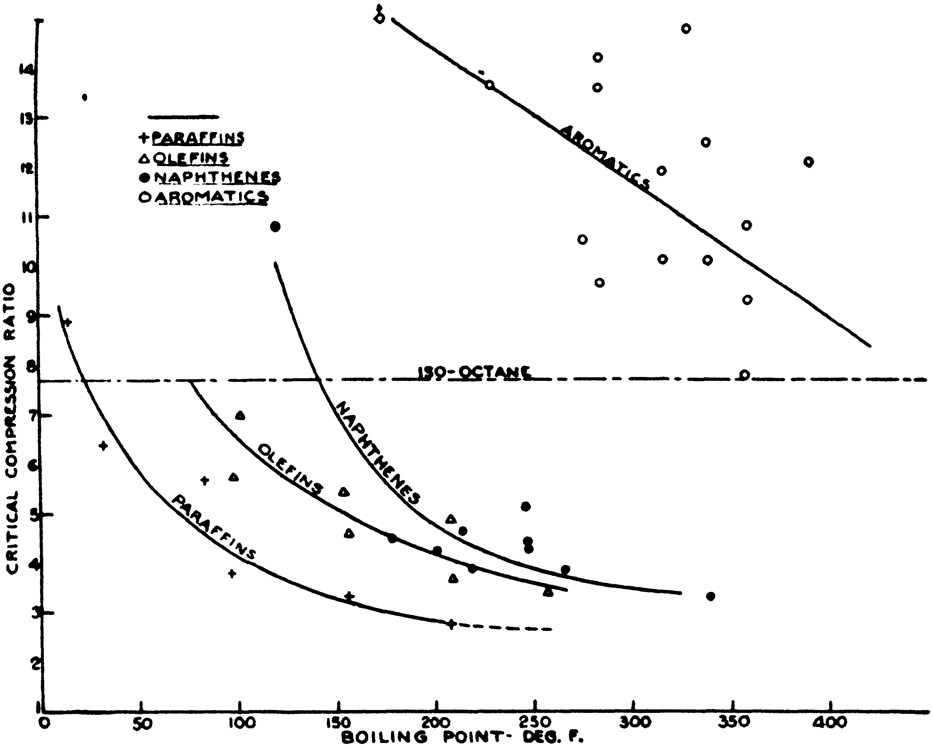
The relationship between antiknock rating (expressed as the octane number) and the structure of the hydrocarbon has been discussed by Kaplan and Forney.[182]



Courtesy National Petroleum News

FIG. 46.—Relationship Between Antiknock Properties and Boiling Points of Hydrocarbons. (W. Kaplan and W. E. Forney)

Fig. 46 shows the relation between the critical compression ratio [a function of the antiknock value[183]] and the boiling points of the various classes of hydrocarbons with isooctane as standard. Thus, the lower paraffins possess good antiknock qualities, but this property drops off in the higher members of the series. The olefins as a class possess better antiknock qualities than the paraffins, but, in this case, their stability is a factor which must also be considered. The naphthenes allow the use of higher compression ratios and at the same time are stable chemically. The higher boiling members of all three of these series are very much inferior in their detonating characteristics to isooctane. The aromatics, however, are characterized by an exceptionally high antiknock rating, exceeding even that of isooctane. Despite this quality, Kaplan and Forney state that motor benzol (which contains principally benzene) is undesirable in itself as a motor fuel because, due to its narrow boiling range, it does not allow smooth motor operation under constantly varying conditions.[184] Furthermore, benzene possesses too high a freezing point. Thus, it will be seen that the octane number alone does not determine the usefulness of a cracked product as a motor fuel.[185]

[184] In this respect, B. K. Tarasov and V. P. Govakov (*Grosnenskii Neftyanik*, 1934, **4** (6-7), 33; *Chem. Abs.*, 1935, **29**, 2716; *Brit. Chem. Abs.* **B**, 1935, 1030) have shown that mixed-phase cracked gasolines give a very irregular octane equivalent curve on being broken up into 5°C. fractions.

[185] G. G. Brown and S. C. Singer, Jr. (*Nat. Pet. News*, 1934, **26** (23), 21; *Oil and Gas J.*, 1934, **33** (10), 80; *Brit. Chem. Abs.* **B**, 1935, 212; *Chem. Abs.*, 1934, **28**, 6990) have stated that gasoline mileage depends upon the heating value per gallon rather than the octane number. According to G. Egloff (*Refiner*, 1935, **14**, 8306; *Chem. Abs.*, 1935, **29**, 8306) cracked fuel contains about 5 per cent more B.t.u. per gallon than the corresponding straight-run fuels.

Table 35 shows the composition of various cracked gasolines and the conditions under which they were produced. The low yields of paraffins and naphthenes and high yields of aromatics both in reforming straight-run gasoline and in cracking gas oil in vapor-phase processes are characteristic.

The researches of Morrell and Egloff[186] on the effect of cracking on the group composition of hydrocarbon distillates are summarized in Table 36. The feed stocks varied from non-aromatic (Pennsylvania naphtha distillate) to high aromatic (pressure distillate bottoms derived from Midcontinent crude oil) in character. The kerosene distillate and straight-run gas oil were also derived from a Midcontinental crude oil. Cracking operations were carried out in the vapor-phase with temperatures ranging from 900° to 1300°F. (480-705°C.). From the data it will be seen that an increase in the reaction temperature causes an increase in the aromatic and olefinic content of the gasoline formed from all of the charging stocks. At the same time, the coke and gas production also rises with elevation in temperatures. Above 1200°F. paraffins and naphthenes are entirely absent in the cracked hydrocarbons.

Zelinskii and Levina[187] have stated that gasolines produced by vapor-phase methods have a total cyclic content (naphthenes and aromatics) of twice that of products from mixed-phase operations (70 to 80 per cent and 30 to 40 per cent, respectively). Butkov and Ostrovai[188] obtained a 14.5 per cent conversion to gasolines of an aromatic content of 94.3 per cent by cracking Baku gas oil at 675°C. (1250°F.) and atmospheric pressure. These investigators stated that by recycling the residual oil, both the yield and aromatic content of the motor fuel may be increased.

The low temperature carbonization of Barzass sapropelites is reported by Kuruindin and Ivanov[189] to result in a high octane number gasoline. The product

is predominantly olefinic (44 to 48 per cent). The proportions of the other types of hydrocarbons are paraffins, 25 per cent, naphthenes, 5 per cent, and aromatics, 22 to 26 per cent.

CHEMICAL CONSTITUENTS OF LIQUID PRODUCTS OF CRACKING

The individual hydrocarbons present in gasoline are extremely numerous and vary with the methods used in cracking the original stock. Moor and Katzman[190] investigated the low-boiling fraction (30 to 45°C.) obtained by the distillation of a gasoline produced by vapor-phase cracking at 570°C. This fraction consisted principally of isomeric pentenes, of which trimethylethylene (2,2-dimethylpropene) and possibly small amounts of *unsym.*-methylethylethylene (2-methyl-1-butene) comprised 17 per cent and 2-pentene and 1-pentene totaled 42 per cent. In addition, 6 to 8 per cent of cyclopentadiene, 10 to 12 per cent of isoprene (2-methyl-1,3-butadiene) and 3 to 7 per cent of piperylene (1,4-pentadiene) were also believed to be present. In this connection, it is interesting to note that Kazanskii, Plate and Artyunyan[191] obtained approximately the same results in their examination of the liquid residue remaining from the distillation of butadiene obtained by cracking kerosene. The portion of this residue boiling between 30° and 52°C. (amounting to 3 per cent of the total) was a mixture of pentenes, piperylene, and possibly isoprene. The other identified components of the residue were: benzene, 55 per cent; toluene, 9 per cent; and cyclopentadiene, 12 per cent.

Potolovskii and Prozumentik[192] have analyzed gasoline recovered from cracked gas and report the following constituents, in per cent: butane and butenes, 10; pentane and pentenes, 20; hexane and hexenes, 12, and higher hydrocarbons, about 58. The composition of the gasoline produced by cracking sapropelite tar has been discussed by Karavaev, Rapoport and Bashkirov.[193] These observers fractionated the gasoline into very narrow cuts and found the following substances: pentane, hexane, heptane, octane, hexene, heptene, octene, nonene, decene, undecene ($C_{11}H_{22}$), cyclohexane, methylcyclohexane, 1,4-dimethylcyclohexane, benzene, toluene and *o*- and *m*-xylenes. Besides the 4 aromatics just mentioned, Kaplan and Forney[194] suggest the inclusion of the following aromatic hydrocarbons: *n*-propylbenzene, isopropylbenzene, *n*-butylbenzene, *sec*-butylbenzene, isobutylbenzene, *n*-amylbenzene, isoamylbenzene, *o*- and *p*-methylethylbenzene, *o*- and *p*-diethylbenzene, *o*- and *p*-methylisopropylbenzene, mesitylene (1,3,5-trimethylbenzene), pseudocumene (1,3,4-trimethylbenzene) and naphthalene. The presence of these hydrocarbons was indicated by the boiling point, specific gravity, refractive index, and molecular weight determinations made on cuts of 5°F. boiling range. The gasoline used for the tests was obtained by the vapor-phase cracking of gas oil. Kuruindin and Shumilov[195] report the presence of cumarone (4.3 per cent)

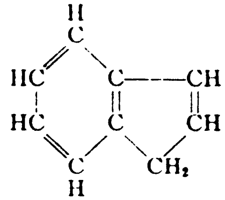
and indene



in the 150-175°C. fraction of a gasoline obtained in the distillation of Cheremkhov coal tar.

Undecene ($C_{11}H_{22}$), dodecene, tridecene, tetradecene, heptadecene and octadecene ($C_{18}H_{36}$) have been identified in the kerosene fractions of Barzass sapropelite tar, according to Karavaev and Karzhev.[196] Karavaev, Rapoport and Kholler[197] have isolated acids from formic up to propionic among the liquids obtained by the dry-distillation of these same tars. From the boiling points and esterification values of the methyl esters, the evidence of several higher acids is also indicated. Charrin[198] has reported phenols, paraffin wax, asphalt and pyridine bases in the tar obtained from Creveney pyroschists.

Chemical Composition of Coke

The significance of coke formation and an explanation of the mechanism have already been considered in this chapter. However, the nature of petroleum coke is such as to merit a brief discussion. Petroleum coke is not elementary carbon but consists of complex, high-molecular weight hydrocarbons containing small percentages of hydrogen. According to Trusty,[199] carbon disulphide will dissolve about 50 per cent of most cokes. Aromatic compounds such as anthracene, phenanthrene, chrysene, picene and crakene ($C_{24}H_{18}$) have been identified as constituents in various petroleum cokes. The structures of some of these compounds are shown below. As an example of the degree of unsaturation, picene, for instance, is 95 per cent carbon and 5 per cent hydrogen. The cokes thus resemble the tars from cracking stills in their general nature. The same types of compounds are formed in these two products, but in the former case the hydrocarbons are in a more condensed form.

Ginzburg[200] gives the proximate analysis of coke obtained from heavy bottoms as 0.84 per cent ash and 5 to 6 per cent volatile matter.

USES OF CRACKED PRODUCTS

Although the production of motor fuels from crude oils is the aim of cracking processes, this cannot be accomplished without the accompanying by-products, gas, tar and coke. The problem of utilization of these latter substances has formed the basis of an enormous synthetic industry of wide applications.[201]

Cracking gases rich in olefins may be converted into alcohols[202] and halides[203] or may be polymerized catalytically to form "polymer" gasoline.[204] Potolovskii and Anfinogenov[205] have used gases from vapor-phase cracking (containing 50 per cent ethylene) in place of acetylene for cutting and welding metals. Butkov and Rabinovich[206] determined the heating value of vapor-phase cracking gases to be 11,000-11,500 cals. per liter, and propose to use these gases as city gas, as others in the past have been. Gases rich in lower paraffins may be recracked at elevated temperatures in the presence of catalysts to form olefins which may subsequently be polymerized into liquid products.[207] This, however, is described in Chapters 2 and 26.

The liquid products also form a source of raw materials. Hall and Bachman[208] obtained 1-pentyne and 1-hexyne by brominating and dehalogenating[209] the corresponding olefins fractionated from a vapor-phase-cracked gasoline. Zilberman,

Bolotin and Yakubovich[210] found that cracking residues reduce the oil adsorption capacity of pigments and believe that these residues may be substituted for linseed oil to the extent of 75 per cent in some coating compositions.

The tar obtained in cracking hydrocarbon oils at high temperatures and pressures contains resins which may be extracted from the residue by means of solvents, such as kerosene or naphtha.[211] These synthetic resins, being unsaponifiable, may be used for a variety of purposes. Frolich[212] suggests mixing about 1.5 per cent of petroleum resins with rubber compositions to improve the softening qualities and reduce the tendency of the rubber stock to adhere to the mill rolls. The addition of this type of resin has no effect on the curing time. Ellis[213] has proposed to incorporate these resins into paper ply and paperboard to provide greater strength and rigidity. Thus, the sheets of cardboard are coated with an emulsion of petroleum resin and water (formed by melting the resin and mixing with water and bentonite), pressed together, heated and calendered in a rolling machine to obtain uniform thickness. The resin emulsion may also be added to paper pulp as a sizing or an impregnating agent. The resins may be dissolved in gasoline and naphtha, mixed with a drying oil, and used as a paint.[214] The addition of wax is suggested for a waterproofing paint, the wax rendering the resins non-sticky but somewhat plastic when the paint is partially dry. Also, incorporation of a plasticizer such as benzene sulphonic acid increases the adhesion of the paint to metallic surfaces. Wood may be impregnated and stained with resins of such type[215] by heating them under pressure immersed in a solution of the resin in molten paraffin wax.

Chapter 4

Production of Unsaturated Hydrocarbons by Pyrolysis

MONOLEFINS

Olefins are produced by thermal decomposition of various types of hydrocarbons and over a wide range of cracking conditions. The lower monolefins, which are important chemical intermediates, are obtained, for the most part, by the pyrolysis of paraffin hydrocarbons. Cycloparaffins also yield substantial proportions of olefins by thermal decomposition in the absence of catalysts but aromatics furnish only small proportions under the same conditions. Cracking of the lower paraffin hydrocarbons receives special attention in this chapter since they are available in large quantities and constitute the most promising raw materials.

In the pyrolysis of the lower paraffins, dehydrogenation to an olefin of the same number of carbon atoms is a relatively unimportant reaction except in the case of ethane and less so in the case of propane and isobutane. In general, decomposition of the molecule occurs mainly by rupture of the carbon bonds so that the olefins produced are lower in molecular weight than the parent paraffin.

The fundamental factors which influence the formation of olefins from aliphatic hydrocarbons are temperature, time of contact, pressure and nature of contact surface. Of these, temperature and time of contact are by far the more important and to some extent are mutually interchangeable. Thus, the results of cracking at low temperatures and long times of contact may be closely simulated by operating at somewhat higher temperatures and at shorter contact times. Since monolefins are usually primary decomposition products of paraffin hydrocarbons, contact time must be carefully controlled otherwise the olefins initially formed may be degraded or aromatized by too long heating periods. When a number of olefins are generated simultaneously by decomposition of a particular paraffin hydrocarbon, the evidence available indicates that the relative proportions at small conversions (i.e., short contact times) are but little influenced by temperature. However, with longer contact times the higher olefins tend to be partly converted into those of lower molecular weights so that ethylene ultimately becomes the main olefinic constituent of the reaction gas. In general, the optimum cracking temperature for olefin production from paraffin hydrocarbons varies considerably but 700°C. is a fair average temperature.

Often, temperatures used in the laboratory for pyrolysis observations are so much higher than those of industrial cracking that the discrepancy is noticeable. It should be remembered, however, that the implements of the laboratory far more easily permit the study of pyrolysis through a higher range of temperatures than sound commercial policy would indicate.

The influence of the pressure factor is not, however, perfectly clear. Since the primary decomposition reactions of paraffin hydrocarbons are homogeneous and first order, pressure should have little influence on the velocity of decomposition.

That this is approximately true has been demonstrated by a number of investigators. For example, the work of Munday[1] on the pyrolysis of *n*-pentane shows that the reaction velocity was approximately constant over a range of partial pressures of 0.1-1.0 atmospheres. Similar results have been obtained by Lang and Morgan[2] on the cracking of propane-steam mixtures at 700°C. On the other hand, however, it has been stated that reduction in pressure in the cracking of petroleum at 600-700°C. causes an increase in the rate of decomposition and a lowering in the temperature at which decomposition begins.[3] From the point of view of the production of olefins by pyrolysis the importance of the pressure factor probably resides mainly in its influence on the condensation and polymerization of the olefins initially formed. Such reactions are bimolecular and are thus favored by increase of pressure. Hence, it is advantageous to operate at low pressures, better sub-atmospheric, so as to minimize polymerization and condensation of the olefins produced. This is conveniently effected in vapor phase operations by employing an inert diluent gas, such as steam, thus reducing the partial pressure of the reacting hydrocarbon.

In the cracking of hydrocarbons (to olefins) it is usually best to avoid the use of heating surfaces, such as iron, nickel and some nickel alloys, which catalyze decomposition into carbon and hydrogen. Certain catalysts have been shown to accelerate dehydrogenation of paraffin to olefin hydrocarbons, but their applications appear to be limited because dehydrogenation is relatively unimportant except in a few cases, irreversible rupture of the carbon chain predominating in most instances. Gauzes of a copper-tin alloy, especially if treated with molybdic oxide, were found by Cambron[4] to aid the pyrolysis of ethane. Frey and Huppke[5] used a special chromic oxide gel in their investigation of the equilibria involved in the dehydrogenation of the lower paraffins. Boeckeler[6] studied various catalysts and ranked the materials tested in the following order of decreasing activity: copper gauze, zinc-copper on pumice, nickel gauze and stainless steel. However, none of these substances exhibited marked activity but merely lowered the temperature at which a given extent of reaction could be obtained without influencing the character of the reaction. Nickel, cobalt, copper or zinc, with or without promoters, have been recommended as contact agents for the pyrolysis of methane.[7] A reduced zinc oxide-chromium oxide catalyst has been suggested by Frolich and Boeckeler[8] for the production of olefins from paraffin hydrocarbons higher than methane. Passage of propane at 635°C. over this mixed oxide yielded a gas containing 14.3 per cent propene, 0.2 per cent ethylene, 26.1 per cent hydrogen and 59.4 per cent residual propane.

The work of Cambron and Bayley[9] indicates that when pyrolysis is carried out under conditions of turbulent flow the yields of olefins, at a given temperature, are greatly increased over those obtained with streamline flow. Furthermore, with turbulent flow higher rates of conversion of the lower paraffins to olefins are possible since the temperatures at which side reactions become important are considerably higher than when the gas flow is streamline. This influence of turbulent flow is associated with the more rapid transmission of heat from the tube walls to the body of the gas and to the elimination under such conditions of the stagnant superheated gas film on the tube wall which is so characteristic of streamline conditions. Rapid heat transmission is essential for olefin formation since all the reactions furnishing olefins from paraffin hydrocarbons are highly endothermic. The approximate heats of reaction of a number of these are as follows:

PRODUCTION OF OLEFINS FROM THE LOWER PARAFFIN HYDROCARBONS

As raw materials for the production of the lower olefins, which are of increasing importance in industrial synthesis, the lower paraffin hydrocarbons have obvious advantages since they are available in large quantities at a low price and their conversion to olefins can be readily accomplished with satisfactory yields.

The importance of turbulence has been demonstrated by the work of Cambron and Bayley,[10] who attained the necessary conditions by the use of silica tubes supplied with circular mica baffles spaced at distances of about 2 cm. apart. The effect of baffles in increasing the output of olefins in the pyrolysis of ethane, propane and *n*-butane is shown by the results obtained with a glazed quartz tube 2.0 cm. in diameter. (See Table 37.) The heated zone was 18.5 cm. in length.

"	*n*-Butane	922°	83.3	1.3	18.3	15.0	2.1	12.6	210.4

A systematic examination was made by Cambron and Bayley[11] of the effect of temperature and time of contact on the yield of olefins from ethane, propane and the butanes in baffled silica tubes. Their results indicate that, for a particular gas rate, the pyrolysis temperature for a given conversion to olefin could be materially reduced by increasing the length of the cracking zone. For example, the temperature required to convert 70 per cent of propane to olefins in a 20 cm. tube was 1087°C. but this was reduced to 960°C. in the case of a 40 cm. tube and to 885°C. by using a 80 cm. tube. This point is of practical significance since the latter temperature is not so severe as to exclude the possibility of using heat-resistant alloy steel tubes. These workers[12] have also reported on the pyrolysis of propane and *n*-butane in empty and baffled tubes constructed of certain heat-resistant alloys. Two alloys were investigated, one of the KA2S type containing about 18 per cent chromium and 8 per cent nickel, and another of a special alloy containing 28 per cent chromium and only traces of nickel. In both cases it was found advantageous to employ baffles to increase olefin production, and reduce the working temperature to the range of utility of special alloy steels. The KA2S alloy gave rise to considerable amounts of carbon, probably owing to the catalytic action of the nickel in the alloy. Tubes of the high-chromium alloy were, however, much better since only negligible carbon formation took place. It was noted, moreover, that the 28 per cent chromium alloy tube tended to deform slightly at 840°C. though no noticeable deformation occurred at 800°C. It was thought that any difficulty due to sagging could be eliminated by providing an adequate number of supports so as to decrease the unsupported length of tube in the furnace. It is reported,[13] nevertheless, that tubes of this alloy have been in successful use for over two years in vapor-phase cracking units operating at 870°C. Some results of Cambron and Bayley on the pyrolysis of propane in the chromium alloy tube (baffled) are given in Table 38.

Data on the production of ethylene and propene by pyrolysis of ethane and propane, respectively, at atmospheric pressure in helical KA2S tubes have been furnished by Sullivan, Ruthruff and Kuentzel.[14] The highest yield of ethylene was obtained from ethane at a temperature of 844°C. and at a contact time of 0.65 second. Under these conditions, conversion was 74 per cent and the exit gas contained 39 per cent of unsaturated hydrocarbons. In the case of propane, an 82 per cent conversion, calculated on a volume basis, into olefins (mainly ethylene) was secured at 820°C. with a contact time of one second. Because the major portion of the propane reacting formed ethylene and methane, the weight yield of olefins was appreciably lower than the volume yield. The influence of contact

The work of Frolich and Wiezevich[15] on the pyrolysis of propane and *n*-butane in silica reactors is of considerable interest in showing the effect of temperature on the olefin content of the exit gas, the contact time being maintained constant. The experimental results for propane are shown graphically in Fig. 49, from which it is seen that the olefin content (of the exit gas) is largest at about 880°C.

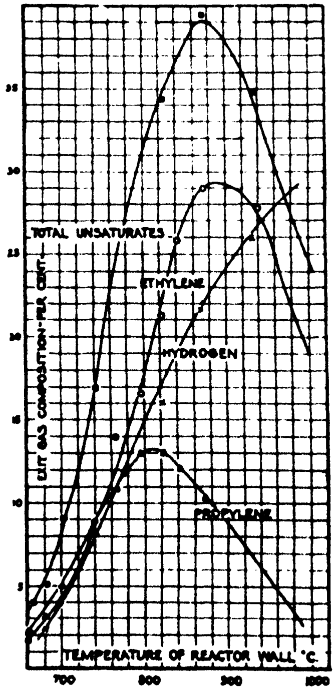

FIG. 49.
Olefin Content of Exit Gases from Propane Cracking at Various Temperatures. (P. K. Frolich and P. J. Wiezevich)

---

[15] P. K. Frolich and P. J. Wiezevich, *Ind. Eng. Chem.*, 1935, 27, 1055; *J. Inst. Pet. Tech.*, 1935, 21, 408A; *Chem. Abs.*, 1935, 29, 7624; *Brit. Chem. Abs.* B, 1935, 980.

The maximum concentration of propene (13.2 per cent) occurred at a lower temperature, namely 810°C., than that, 890°C., required for the maximum concentration of ethylene (29.4 per cent). In the case of *n*-butane (Fig. 50) the greatest total olefin content of the reaction gas was obtained at 690°C. The temperature at which the propene concentration is at a maximum (11.1 per cent at 650°C.) is somewhat lower than that (730°C.) for maximum ethylene content, namely 29 per cent. The highest concentration of butene, 8.1 per cent, was secured at about 670°C.

Interesting results have been reported by Frolich and Wiezevich on cracking propane in a copper tube in the presence of about 70 per cent of air in the inlet gas. Under these conditions 75-80 per cent of the propane was converted into unsaturated hydrocarbons at 675° ± 15°C. and a contact time of about 30 seconds. The unsaturated hydrocarbons formed consist of ethylene and propene in the ratio of 3 parts of ethylene to 2 of propene. The conversions obtained in the presence of air may be compared with the optimum conversion of 60-70 per cent by straight cracking at 700°C. using a copper-coated steel reactor. When air was admixed with propane, Frolich and Wiezevich noted that the material constituting the reactor exerted some influence on the course of reaction. At temperatures below 560°C. a mild steel reactor gave higher yields of unsaturated hydrocarbons than one of copper. At 600°C. and above, copper was much more satisfactory since at these temperatures iron apparently catalyzed polymerization of the olefins into liquid and solid tars. In the presence of air, glass seems to exert a slight inhibiting action on the cracking.

PRODUCTION OF LOWER OLEFINS FROM HIGHER HYDROCARBONS

The production of the lower olefins by pyrolysis of pentanes, hexanes and heptane in baffled quartz tubes at temperatures of about 1000°C. has been inves-

tigated by Cambron and Bayley.[16] Typical results obtained by these investigators using a silica tube (20 cm. long and 2.7 cm. internal diameter) with mica baffles are given in the appended Table 39.

TABLE 39.—*Pyrolysis of Paraffin Hydrocarbons in Baffled Silica Tube.*

It is evident that pyrolysis of the lower liquid paraffins can be controlled to yield gaseous products containing 50-55 per cent by volume of olefins consisting of approximately equal amounts of ethylene and propene. The experiments summarized above were all characterized by the absence of tar formation and carbon deposition in spite of the high temperatures employed and the high concentration of olefins in the gaseous products.

Matignon and Seon[17] report that water vapor exerts a marked influence on the yield of ethylene (and its homologues) from heptane.[17a] For example, these investigators observed that in the absence of water and at 700°C. the paraffin gave 39 per cent of ethylene. On the other hand when the ratio of heptane to water vapor was 2:7 (by weight) and the temperature 800°C., 50 per cent of ethylene was obtained. Increasing the proportion of water to paraffin (5:2) and the temperature (to 935°C.) raised the yield to 76 per cent of ethylene.

Danaila and de Bie[18] investigated the production of ethylene by vapor-phase cracking, at 600-720°C. under an absolute pressure of 150 mm., of a light kerosene fraction. Under these conditions 70-95 per cent of the oil was converted into gas containing substantial proportions of ethylene while no low boiling liquids were formed. At 740-750°C. carbon formation is less than 3-4 per cent of the oil used. Reduction of pressure was found to lower the initial decomposition temperature of the oil and to increase the proportion of ethylene in the gas. If aromatic hydrocarbons are removed from the oil prior to pyrolysis, a gas containing 45 per cent of ethylene can be obtained, representing 47 per cent of the oil employed. Separation of the higher olefins from this gas raises the ethylene content to over 55 per cent by volume.

In the cracking of gasoline and kerosene fractions (from the same crude oil) in a quartz tube, optimum olefin production, according to Candea and Kühn,[19] occurred at temperatures of 700°C. and 600°C., respectively. High olefin yields were favored by short heating periods.

The decomposition of the higher boiling fractions (Kogasin II) of the paraffinic benzine obtained from hydrogen and carbon monoxide by the Fischer-Tropsch process,[20] has been studied by Pichler.[21] The reaction, carried out in narrow tubes to enhance the ratio of heating surface to reaction volume and to avoid overheating of the walls, furnished up to 75 per cent of gaseous olefins together with volatile, liquid, aromatic and unsaturated hydrocarbons, the remaining 25 per cent consisting of saturated gaseous hydrocarbons, undecomposed paraffin oil and aromatic tar. Above 600°C., gaseous olefins predominated in the products, the yields rising from 20 per cent by weight at 550°C. and 0.4 second contact time to 62 per cent at 700°C. and 0.14 second. Similar results were secured by pyrolysis of Kogasin II with an electrically heated platinum wire. Under the latter conditions, the products consisted of 20 per cent of highly unsaturated liquid and 80 per cent of gaseous hydrocarbons. Of the latter, 70 per cent (by volume) were unsaturated and consisted principally of ethylene or its homologues.[22] Use of an electrically heated graphite rod in place of the platinum wire gave 14.7 per cent liquid and 85.3 per cent gaseous products.[22a] The latter contained 12.7 per cent hydrogen, 69 per cent unsaturated and 18.3 per cent saturated hydrocarbons.

Candea and Manughevici[23] studied the thermal decomposition of a Rumanian kerosene fraction both in the presence and absence of catalyst. Best yields of ethylene were obtained at 800°C. and the use of copper surfaces, either in the form of tubes or shavings in glass reactors, was found to impede carbon formation.

It is interesting to note that ethylene may be prepared from peat or cracked tar at 600-700°C. by air-blowing.[24] Aluminum and ferric oxides apparently have no catalytic effect on the reaction. In some instances alcohols may serve as the source of olefins. For example, Sakmin[25] made ethylene by passing ethyl alcohol over unglazed porcelain in a copper tube at 400-500°C. At lower temperatures (300°C.) propene was obtained. Triebs[26] observed that amorphous clay exerted a greater catalytic effect than porcelain. If a pressure autoclave is used, a temperature of 200-350°C. is necessary. Ipatieff[27] points out that pure copper is not a catalyst for the decomposition of alcohols, and he recommends alumina.

HIGHER OLEFINS BY PYROLYSIS

The production of higher olefins, for example, pentene, hexene and higher, is intimately associated with the cracking industry. Gasolines from commercial cracking processes, especially from so-called vapor-phase operations at 500-600°C., are relatively rich in olefin hydrocarbons. A discussion of the various types of unsaturated hydrocarbons found in such gasolines is given in Chapter 3, from which it will be seen that the available information is still incomplete.

It is interesting to note that both indene and styrene, two aromatic monolefin hydrocarbons of value in the manufacture of synthetic resins, have been isolated from the products of pyrolysis of Persian natural gas at temperatures of about 850°C. Using a gas rich in propane and butane, the yields of styrene and indene are about 2.4 and 0.95 liters, respectively, per 100 cubic meters of gas pyrolyzed. Birch and Hague[28] consider that the most probable mechanism of the formation of styrene is by direct combination of ethylene and benzene to furnish ethylbenzene, which can then dehydrogenate to styrene.

---

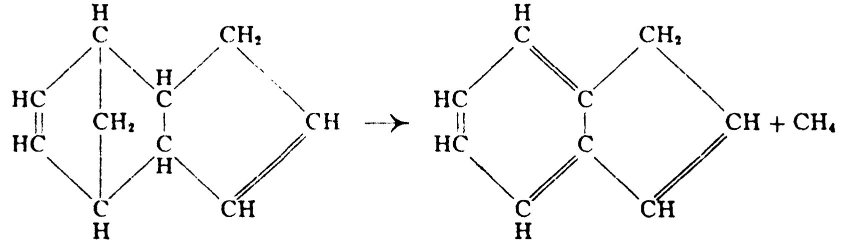
It is not so easy to account for the indene, which might be formed (1) by reaction between propene and benzene to give propylbenzene, convertible into indene by ring closure and dehydrogenation; (2) by a somewhat similar reaction between toluene and ethylene involving the formation of ethyltoluene or propylbenzene followed by ring closure and dehydrogenation or (3) by demethanation of dicyclopentadiene as follows:



The suggested mechanism for the formation of styrene was confirmed by pyrolysis of an equimolecular mixture of ethylene and benzene at 820°C., the products containing 40 per cent of styrene in the fraction boiling higher than benzene. No experimental evidence could be obtained in support of any of the suggested reactions for the formation of indene.

TECHNICAL PROCESSES FOR OLEFIN PRODUCTION

The influence of pressure on the production of olefins by pyrolysis of saturated hydrocarbons has already been discussed and it has been shown low partial pressures are favorable since polymerization and condensation reactions are thereby largely suppressed. High temperature pyrolysis at pressures below atmospheric is hardly practicable on an industrial scale so that a diluent is usually employed to reduce the partial pressure of the reacting hydrocarbon vapors. Steam is often used for this purpose but the oxides of carbon, e.g., 5-20 per cent of carbon dioxide, are suggested by Dreyfus.[29] Instead of subjecting the mixture of hydrocarbon vapor and inert diluent gas to heat treatment, the latter may be preheated to a sufficiently high temperature so that on incorporating with the hydrocarbon vapor the resulting blend is at a temperature high enough to effect pyrolysis.[30] Thus, Grebe, Coleman and Reilly[31] produce gaseous olefins by adding oil vapors to sufficient steam, superheated to 950-1200°C., so that the resulting mixture attains a temperature of about 800-1000°C. An electrical heating coil, shown in Fig. 51, may be employed for increasing the temperature of the steam. The reactants are then passed over magnetic iron oxide.

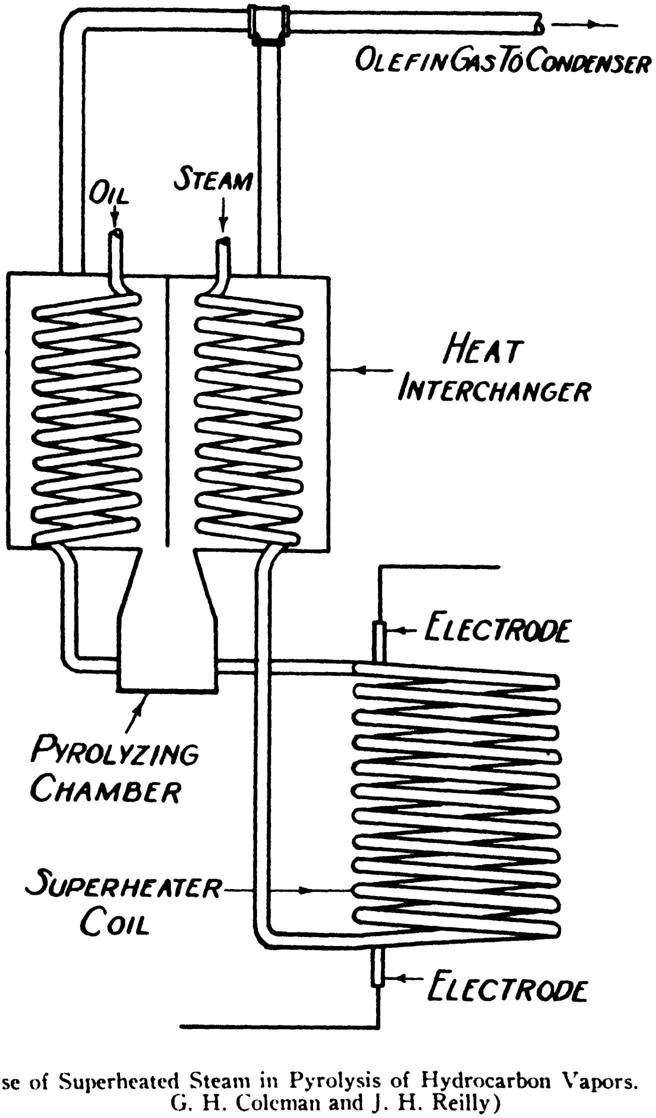

FIG. 51.—Use of Superheated Steam in Pyrolysis of Hydrocarbon Vapors. (J. J. Grebe, G. H. Coleman and J. H. Reilly)

An apparatus for cracking hydrocarbon vapors at 600-1200°C. and 0.005 to 0.1 second contact time is described by Tropsch.[32] It consists of a vertical annular vessel, placed in a down-draft furnace, and heated by flames impinging on the inside and outside near the lower end through which the hydrocarbons are admitted to the reaction zone.

---

[32] H. Tropsch, U. S. P. 1,981,129, Nov. 20, 1934, to Universal Oil Products Co.; *Brit. Chem. Abs.* **B**, 1935, 882; *Chem. Abs.*, 1935, **29**, 474. *Cf.* U. S. P. 2,045,255, June 23, 1936; *Chem. Abs.*, 1936, **30**, 5597.

Instead of using an externally heated tube, it has been proposed[33] to employ a converter filled with refractory material which is first raised to a sufficiently high temperature by downward passage of hot gaseous products of combustion. After removal of the latter by a current of steam or gas, pyrolysis of gaseous hydrocarbons is effected by passage of these in an upward direction over the refractory material. The cycle is then repeated. When natural gas is the raw material, a portion of this may be burned thus heating the reaction zone to 800°C.[34] During combustion untreated gas is introduced, and the resulting product is a mixture having a B.t.u. value of about 800.

Dreyfus[35] produces unsaturated hydrocarbons from paraffins (boiling below 150°C.) by conducting their vapors through organic liquids or semi-liquids (containing suspended carbon) at temperatures of 300-350°C. For example, a gas consisting of ethane and propane is pyrolyzed by passage, under 5 atmospheres pressure, through a cracking residuum at 450°C.

A number of catalysts have been described for the preparation of olefins from paraffins (usually by dehydrogenation), examples of such being sulphur, arsenic, antimony, selenium or tellurium.[36] Other contact agents include zinc chloride[37] and coke.[38] A small proportion of a halogen, such as iodine, is said to accelerate formation of olefins from propane at 575-650°C.[39] Catalysts consisting of the halides of copper, silver, zinc, cadmium, thallium, tin, lead, titanium, silicon, vanadium, bismuth, molybdenum, tungsten, uranium, manganese, rhenium, nickel, iron and cobalt or of the elements selenium, tellurium, arsenic, antimony, or carbon are reported[40] to effect dehydrogenation of normally liquid saturated hydrocarbons at temperatures of 200-500°C. In some instances, hydrogen chloride or chlorine may be admixed with the hydrocarbon vapors, and the latter conducted over metals (e.g., manganese or zinc) at 400-500°C.[41] Difficulty reducible oxides or sulphides, such as tungstic oxide on carbon, may be employed with solid paraffin hydrocarbons at 400° to 500°C. and atmospheric or reduced pressures.[42] Dreyfus[43] prepares ethylene (and also ethane) by conducting methane over a catalyst (nickel, cobalt, copper or zinc) at 350-850°C. Pyrolysis of gaseous hydrocarbons at 400-1100°C. in the presence of 2 per cent of mercury[44] or 0.01 per cent of cadmium[45] vapor has been suggested. Also, it has been pointed out that the oxides of bi- and trivalent chromium may be employed.[46] It is reported[47] that dehydrogenation of higher paraffin hydrocarbons, without substantial rupture of carbon bonds, can be effected at 800-900°F. and at about atmospheric pressure in the presence of catalysts such as alumina, thoria, and the oxides or sulphides of the metals of Group 6 of the Periodic Table.

The cracking of ethylbenzene to styrene may be accomplished at about 500-700°C. in the presence of ceria or zinc and an oxide of tungsten, uranium or molybdenum.[48]

The development of construction materials for tubes used in the pyrolysis of saturated hydrocarbons has been the subject of much investigation. Not only must the tubes be capable of withstanding the necessary high temperatures for prolonged periods of time but they must not catalyze carbon formation and should accelerate the olefin-forming reactions. Special heat-resisting alloys or refractory silicious materials have been employed for this purpose but the latter suffer from the disadvantage of low mechanical strength, thus necessitating the use of comparatively thick-walled retorts with consequent poor heat transfer. In the large scale pyrolysis of Persian natural gas, a special alloy steel (H.R.4) containing 26 per cent of chromium and not more than 0.3 per cent nickel was found most applicable.[49] Prolonged contact of this alloy at temperatures of about 1000°C. resulted in some embrittlement, which may be suppressed by an increase in the nickel content. Reference has already been made to the tests carried out by Cambron and Bayley using high-chromium steels.

Pyrolysis of saturated hydrocarbons, diluted with steam, may be effected at 600-900°C. in reactors consisting of a chromium steel containing less than 2 per cent of nickel or of iron of low nickel content and externally coated with a layer of heat-resisting chromium-nickel steel.[50] Alloys containing 50-80 per cent of nickel, 10-25 per cent of chromium and 4 to 30 per cent of iron have been used at temperatures of 700-1000°C.[51] Externally-heated silicon tubes are reported to show a decided promise in suppressing carbon formation under properly controlled conditions.[52] Parts of apparatus exposed to temperatures above 500°C. may be composed of or lined with a composition containing free silicon which has been molded into tubes (or other shapes) by the usual ceramic processes.[53] Alternatively, internal coatings of a high-melting element, especially silicon or titanium, may be secured by firing the latter in powder form in the apparatus.[54] In some instances, tubes of silicon, or a metal silicide, are encased in steel tubes, a layer of alumina cement being interposed to prevent the formation of an alloy between the silicon and the outer steel casing.[55] For temperatures above 500°C., it has been proposed to use glazes of the silicates, phosphates and borates of copper, manganese, lead or chromium applied internally on supports of refractory material such as the silicides, carbides or chamotte.[56] Internal linings of tin, lead, molybdenum, chromium or tungsten are obtained by decomposition within the apparatus of certain compounds of the metal. Metallic alkyls, carbonyls or volatile chlorides may be employed for this purpose.[57] Winkler and Haeuber[58] propose the use of internally tinned manganese-copper tubes for the production of the lower olefins from gaseous paraffins at about 700°C. In one process it has been recommended that the cracking tube be employed in a vertical position.[59] At the upper end of the latter is placed a reflux condenser which returns unreacted substances to the cracking zone. In this manner the conversion of a coal-oil distillate to olefins is said to be effected.

Pyrolysis of hydrocarbons at atmospheric pressure in the presence of oxygen or oxygen-containing gases is of interest since part of the heat required is supplied by incomplete combustion. The results of Frolich and Wiezevich[60] with propane-air mixtures have already been discussed. The conversion of saturated gaseous hydrocarbons to unsaturated hydrocarbons by heating to 570-1200°C. under practically normal pressure and in the presence of a small proportion of a gas containing free oxygen has been described.[61]

In general, olefins having less than ten carbon atoms may be converted into those of higher molecular weights by heat treatment[62] at 550-650°C. in the presence of not more than 5 per cent oxygen. Herrmann and Baum[63] prepared acetylene by conducting ethylene, with insufficient oxygen for complete combustion, over catalysts at temperatures up to 1000°C. and at space velocities of about 160 liters per liter of reaction space.

Olefin hydrocarbons, containing at least 5 carbon atoms, may be obtained by the vapor-phase cracking of mixtures composed essentially of aliphatic hydrocarbons, for example, paraffin wax or mixtures containing more than 20 per cent of paraffin wax, and submitting the products to fractionation.[64]

In two-stage processes for the conversion of paraffin hydrocarbon gases into liquid hydrocarbons by intermediate formation of olefins and subsequent polymerization of same, it is often proposed to conduct the first stage under pressure. Thus, Wagner[65] pyrolyzes natural gas at 1250-1350°F. under a pressure of 30 lb. per sq. in., the gaseous olefinic portion of the product being removed and polymerized at higher pressures and lower temperatures. In making liquid hydrocarbons from butane and propane, Frey[66] recommends the intermediate formation of olefins be carried out above 540°C. and under a pressure of 1000-5000 lb. per sq. in., and subsequent polymerization be effected at lower temperatures and the same pressure. In another procedure, Coxon[67] passes a stream of natural gas of restricted cross sectional area into a stream of inert gas previously heated above the reaction temperature. The gases unite in a reaction chamber and condensable liquid material is separated as it leaves the heated zone.

Separation of Lower Olefins from Gas Mixtures

Separation of the lower olefin hydrocarbons from gas mixtures containing (in addition to olefins) hydrogen, paraffin hydrocarbons, butadiene, and, in some cases, acetylene is an important technical problem since relatively pure olefins must be employed in certain industrial syntheses. Both chemical and physical methods, including absorption and adsorption, have been suggested for this purpose. A typical chemical mode of segregation may be employed for the production of alcohols from olefins by absorption in sulphuric acid in several stages, each successive stage representing sulphating conditions more or less specific for one particular olefin. Thus, propene and ethylene may be extracted from gaseous mixtures by absorbing the former olefin in 80-90 per cent sulphuric acid at 20-23°C. and 10-25 atmospheres pressure and subsequently absorbing the latter hydrocarbon in sulphuric acid of 75-85 per cent strength at 90-130°C. and 10-25 atmospheres pressure.[68] According to Engs and Moravec,[69] olefins of the type $RCH{=}CHR$ and $R_2C{=}CHR$ may be removed from hydrocarbon mixtures by treatment with 60-70 per cent aqueous sulphuric acid at 0-25°C., whereby they are selectively converted into their sulphuric mono esters. On heating the acid liquor, these mono alkyl sulphates are transformed into polymers of the original olefins. Ethylene or concentrates rich in ethylene are prepared by Markovich and Pigulevskii[70] by first eliminating higher hydrocarbons with sulphuric acid and then treating with organic solvents, compressing, cooling and rectifying under pressure.

Separation of olefins from hydrocarbon gas mixtures by liquefaction under pressure followed by pressure fractionation has been developed by a number of industrial concerns, including The Air Reduction Co. in U.S.A. and the Linde Air Products Co. in Germany. When the olefins and paraffins possess the same number of carbon atoms this procedure is somewhat difficult because of the closeness of physical constants (e.g., vapor pressures) of the hydrocarbons. The physical characteristics of ethane and ethylene, however, are sufficiently divergent to render separation easily possible. A continuous process for the segregation of ethylene from complex gas mixtures has been described by Van Nuys[71] in which the mixture is subjected to selective liquefaction, followed by rectification of the liquid portions. Carney[72] recommends a two-stage fractionating system for the separation of a particular liquid olefin from cracked oils. In the first stage, concentration of the desired product into one fraction is effected by distillation. The latter is subjected to a second rectification to give further segregation of the compound, the residue being returned to the first stage. It is reported by Deanesly[73] that pressure fractionation of liquid olefins from liquid paraffins is facilitated by the presence of liquid ammonia. The latter is said to have a greater affinity for olefins than for paraffins. In the procedure, a mixture of olefins and paraffins is fractionally distilled in the presence of anhydrous liquid ammonia. The distillate is condensed, cooled and led to a separator (Fig. 52). In the latter the ammonia and olefins are drawn off from the lower layer and returned to the still, and the paraffins are removed from the upper portion of the separated distillate. Another example of this procedure is the successive condensation of propene and ethylene followed by fractionation of the individual

[73] R. M. Deanesly, U. S. P. 1,866,800, July 12, 1932, to Shell Development Co.; *Brit. Chem. Abs.* B, 1933, 1046; *Chem. Abs.*, 1932, 26, 4611.

The possibility of isolating olefins from gas mixtures by absorption in selective solvents has attracted considerable attention. In general, it is proposed to subject the gases, under increased pressure, to countercurrent washing with a solvent, the dissolved olefins being subsequently recovered from the liquid by reducing the pressure or raising the temperature, or both. Processes of this kind are readily made continuous and are attractive from an economic point of view. Voorhees and Youtz[76] suggest compressing cracking gas to 5-10 atmospheres, cooling to 20°C. and washing with an aqueous solution of alcohols, such as methyl alcohol, glycol or glycerol. It is stated that ethylene and propene are 5 to 6 times as soluble as the corresponding paraffins in 95 per cent ethyl alcohol. Bennett[77] proposes dichlorethyl ether, amyl alcohol or isopropyl ether for the selective absorption of olefins at super-atmospheric pressures and relatively low temperatures. The greater solubility of propene in mineral oils is utilized by Horsley[78] in his cyclic process for partial segregation of ethylene from propene. The mixed gases are washed under pressure with a mineral-oil fraction, boiling above 200°C., oil is separated and the pressure is released in stages. The gas from the first stage is recycled. Another method comprises scrubbing the compressed olefin fraction with liquid butane and separating the dissolved olefins by distillation under pressure.[79]

Other media which may serve for extraction of olefins from admixtures containing paraffin hydrocarbons are cresylic acid,[79a] liquid sulphur dioxide,[79b] and a blend of furfurol (65 parts) and toluene (35 parts).[79c]

Certain solutions containing monovalent copper salts appear to exert a preferential solvent action on the lower unsaturated hydrocarbons and this fact is utilized in a number of procedures for the removal of olefins from complex gas mixtures. The preferential solvent action is no doubt due to the formation of double compounds with high dissociation pressure. Tropsch and Mattox[80] found that ethylene (under pressure) and solid cuprous chloride yield an addition compound of the formula $CuCl{\cdot}C_2H_4$, the dissociation pressures of which are 2.14 atmospheres at 0°C., 5.95 atmospheres at 16.8°C., 11.70 atmospheres at 30.0°C. and 19.49 atmospheres at 40.0°C. The addition of less than 10 per cent of kieselguhr to the cuprous chloride increases the rate of absorption of ethylene. Propene under pressure does not react similarly. Ethylene was not absorbed under 60 atmospheres pressure by a suspension of cuprous chloride in cold water.

In the process of Watts,[81] ethylene and higher gaseous olefins are removed from gas mixtures by an ammoniacal cuprous salt solution and the dissolved gases are recovered by heating the solution or reducing the pressure. Horsley[82] proposes ammoniacal solutions of cuprous nitrate, salicylate, phenolate or cresolate for the same purpose. He believes such solutions have a higher absorptive capacity than cuprous chloride or formate.

One disadvantage of the use of ammoniacal solutions of cuprous salts is the high volatility of ammonia which tends to be carried forward in the gas stream and whose recovery necessitates special equipment. To overcome these difficulties, Joshua and Stanley[83] employ solutions of cuprous salts in a mixture of water and a hydroxyalkylamine, such as monoethanolamine, diethanolamine, propanolamines and butanolamines. These bases are much less volatile than ammonia so that the necessity of an expensive and troublesome recovery system is obviated. It is also desirable to have present a salt of the base, such as the hydrochloride or the formate, in an amount up to about 1 mole of the salt per gram-atom of monovalent copper. A typical solution for absorbing olefins from gas mixtures is prepared by dissolving 100 g. of cuprous chloride in a mixture of 300 g. of water, 200 g. of monoethanolamine and 75 cc. of hydrochloric acid of density 1.16. The solubility of some gases in this solution at 20°C. and at various pressures is given in Table 40, the solubility being expressed in liters of gas at N.T.P. dissolved by 1 kilogram of solvent.

TABLE 40.—Solubility at Absolute Pressures of:

Gas	1 Atm.	5 Atms.	10 Atms.	20 Atms.
Ethylene	8.4	15.8	21.2	24.2
Propene	1.1	4.3	6.1	—
Butenes	1.0	—	—	—
1,3-Butadiene	11.0	—	—	—
Hydrogen	—	—	0.08	0.17

In practice, the gaseous mixture is washed under pressure with a countercurrent stream of the solvent and dissolved hydrocarbons are recovered by reducing the pressure and warming the solution. By this procedure, gases containing 90 per cent, or more, of mixed olefins are obtained. Since the olefins dissolve in cuprous salt solutions with heat evolution, cooling is necessary during the washing operation. Furthermore, acetylene must be removed from the gases prior to absorption, otherwise cuprous acetylide is formed.

The separation and concentration of ethylene from cracking gas by adsorption on charcoal have been recorded by Pipik.[84] This method, however, requires careful control of the temperature. Displacement of ethylene from charcoal is best effected, not with steam, but with cracking gas. A 2 per cent solution of ethylene was concentrated to 17 per cent and a 25 per cent solution to 55 per cent by this procedure.

Partial segregation of gaseous hydrocarbons has been accomplished by Fussteig[85] by the use of active charcoal contained in two towers in series. By passage of cracking gas, previously dried over calcium chloride, through this system it was possible to condense all the ethylene homologues in the first tower and to retain the ethylene in the second. The olefins were desorbed by wet steam, after which

it was necessary to regenerate the charcoal with steam superheated to 250°C. Butadiene was removed by absorption in a saturated solution of cuprous chloride, from which it could be recovered by warming to 55-60°C. Also, it has been suggested that the propane and butene from coke-oven gases may be isolated by absorption with active carbon.[86] In this case, benzene and hydrogen sulphide must be removed before absorption.

The use of silica gel, activated by heating at 270-280°C. for 3.5 to 4 hours, for the recovery of butene-2 from air containing small concentrations of that hydrocarbon, has been investigated by Volzhinskii, Globov and Khrenova.[87] At 20°C., with a gas mixture containing about 5 per cent of the hydrocarbon, the gel absorbed about 4 per cent by weight of butene-2. Desorption and regeneration were carried out by heating to 200-225°C. but the gel then exhibited a lower adsorptive power.

It is of interest to note that hydrogen can be removed from gases rich in olefins by selective oxidation with oxygen or air in the presence of a catalyst, such as copper oxide, with practically no simultaneous loss of hydrocarbon constituents.[88] Addition of an oxide of carbon to the gaseous mixture and effecting reaction between the oxide and hydrogen has been proposed also.[89]

PRODUCTION OF ACETYLENE

In the pyrolysis of petroleum hydrocarbons, acetylene formation probably begins at about 700°C. and increases with rising temperature. Largest yields from gaseous hydrocarbons appear to be obtained under the following conditions: (1) high temperatures, e.g., the electric arc, for short periods of time, (2) reduced pressures, and (3) the use of a diluent, such as hydrogen or steam, to minimize decomposition to hydrogen and carbon.[90]

On account of its cheapness and abundance methane has been studied extensively from the viewpoint of acetylene production and the experimental data of numerous investigators have been correlated by Storch.[91] The variation of the equilibrium constant of the reaction

$$2CH_4 \longrightarrow C_2H_2 + 3H_2 - 91{,}000 \text{ cal.}$$

is represented in Fig. 53, in which the data has been calculated from the spectroscopic results of Kassel[92] for the free energies of the hydrocarbons concerned. The value of the constant,

$$K = \frac{P_{C_2H_2} \times P^3_{H_2}}{P^2_{CH_4}}$$

varies from 5×10^{-3} at 1000°C. to 250 at 1500°C. Kinetically, the decomposition of methane under conditions of low hydrogen concentration can be represented by the unimolecular equation

The equilibrium constants of the thermal dehydrogenation of ethylene to acetylene

$$C_2H_4 \longrightarrow C_2H_2 + H_2 - 45,800 \text{ cal.}$$

have been calculated by Storch from Kassel's free energy data. The variation of the constant

$$K = \frac{P_{C_2H_2} \times P_{H_2}}{P_{C_2H_4}}$$

with temperature is represented graphically in Fig. 53. The work of Fischer and Pichler[94] seems to indicate that this dehydrogenation is a unimolecular reaction though there is a definite trend towards higher conversions at the lower partial pressures of ethylene. Dilution with hydrogen markedly suppresses polymer formation with the result that acetylene can be made the main reaction product at high temperatures, low pressures and shorter heating periods. Dreyfus[95] reports that ethylene may be converted to acetylene by passage of gas, preheated to 800-1000°C., though an annular space at 1200°C. for a contact period of 0.05-0.01 second, employing hydrogen to reduce the partial pressure of the hydrocarbon to below 1 atmosphere. The results of Fischer and Pichler[96] for the pyrolysis of ethane at low pressures and temperatures of 1000-1400°C. are practically identical with those obtained under the same conditions with ethylene. This probably means that ethane dehydrogenates to ethylene much more rapidly at these temperatures than does ethylene to acetylene.

Pyrolysis of propane, *n*-butane and isobutane at 1100°C. and 50 mm. pressure furnishes considerable amounts of acetylene, the concentration of the latter in the resulting gas increasing with increased contact time.[97]

To obtain substantial yields of acetylene from methane it is necessary to conduct pyrolysis at temperatures as high as 1400-1500°C. and to operate at low partial pressures of methane.[98] In practice, it may not be feasible to carry out this high temperature cracking at pressures below atmospheric so that dilution with a cheap and relatively inert gas would be required for efficient operation. Hydrogen or oxides of carbon have been employed as diluents. When hydrogen is used, Frost[99] points out that a 95 per cent conversion of methane to acetylene can be secured at 1500° absolute and 0.1 atmosphere pressure. From the economic point of view, Storch believes the conversion of methane into acetylene is limited by the necessity of carrying out a highly endothermic reaction at a very high temperature level. Furthermore, the high temperatures needed virtually exclude the use of all constructional material except alundum or silicon carbide. He suggests that the process might be carried out in an intermittent cycle, a checker work of refractory material being first raised to the reacting temperature by burning preheated natural gas and compressed air and then effecting the decomposition of diluted methane in the second stage of the cycle. Storch also points out that conversion of ethylene,

ethane, propane or butane to acetylene by thermal decomposition does not necessitate such high temperatures so that in the case of these higher hydrocarbons the desired temperatures could possibly be obtained with externally heated tubes, for example, tubes of chrome alloy.

In the technical processes which have been described for the production of acetylene from methane or natural gas, some method of internal heating, such as incomplete combustion, is generally proposed. Thus, Fischer and Pichler[100] prepared acetylene by passing a mixture of methane and oxygen, in proportions insufficient for complete combustion, through a reaction zone at above 1000°C. The reaction time was less than 0.01 second. Under proper conditions the ratio of carbon monoxide to hydrogen in the resulting gas is approximately 1:2 so that, after removal of acetylene, the residual gas may be used for the synthesis of benzine. de Rudder and Biedermann[101] suggest mixing methane (or higher hydrocarbons) and hydrogen with sufficient chlorine to heat the mixture to a temperature of 1200°C. or higher by combustion of the hydrogen in the chlorine, after starting the reaction by auxiliary heating. Dreyfus[102] reacts carbon with methane or hydrogen, or both, at above 1000°C., heat being supplied to the reactants by combustion of part of the gas. For example, finely divided carbon may be blown through a flame of burning methane. Also, it has been suggested that methane and finely divided coke be placed in an electric arc.[103] The latter is maintained at 1500°C., and the gases are conducted through the arc rapidly to insure a short period of contact. Treatment in the arc is followed by a sudden cooling of the products. Wulff[104] has disclosed a process in which natural gas is compressed to a sufficient pressure to raise the temperature to at least 1370°C. The pressure is released so that the gases are held under the specified temperature for less than 0.1 second and the expanded gases are rapidly cooled to a temperature at which acetylene is stable. A partial conversion of natural gas to acetylene may be secured by passage at 980°C.[105] over silicon carbide, after which the gases are quickly removed and cooled.

In the process of Binnie,[106] a gas mixture containing equal volumes of methane and hydrogen chloride is passed through a tube of refractory material at a temperature of 1400-1450°C. and at a space velocity of 6000-9000 volumes per minute. In some instances a small proportion of chlorine, not more than 1 per cent of the volume of hydrocarbon gas, may be employed.[106a] The use of subatmospheric pressures of the order of 0.1 atmosphere or less, in conjunction with temperatures of about 1300°C., is recommended by Tramm and Jung[107] for the conversion of saturated or unsaturated aliphatic hydrocarbons into acetylene. Pyrolysis of methane may be effected by passage through an electrical resistance furnace, forming the reaction chamber, in which the heating resistance is made of material of large internal area such as activated carbon.[108] A contact mass of tungsten, heated by induction, is suggested by Eymann.[109] Fused alumina has been suggested also, particularly as a lining for the heated reaction zone.[109a]

In another procedure the hydrocarbons are heated to obtain partial conversion to olefins and the resulting gases then oxidized.[110] For example, a gas consisting mainly of propane is preheated to about 700°C. (to secure about 5 per cent conversion to olefins) and then subjected to partial combustion at temperatures above 1000°C. The products comprise acetylene, ethylene and methane.

SEPARATION AND PURIFICATION OF ACETYLENE

For the extraction of acetylene from dilute gas mixtures, such as those produced by high temperature pyrolysis of hydrocarbons, countercurrent washing with a selective solvent has been usually employed. The scrubbing operation may be conducted under pressure and acetylene is recovered from the liquid by heating and reducing the pressure. Many organic solvents have been proposed for this purpose, including ethers, esters or mixed ether-esters of the polyglycols;[111] an ester of an aliphatic polybasic acid and a monohydric alcohol having 1 to 3 carbon atoms, such as diethyl oxalate;[112] an alkyl carbonate, e.g., diethyl carbonate;[113] and a wide variety of ketones, aldehydes, aliphatic alcohols and their esters, hydrocarbons and chlorinated hydrocarbons.[114] An example of a liquid alicyclic ketone, to be employed as an extraction medium, is cyclohexanone.[115] Lactones, such as butyro- or γ-valero-lactone, have been suggested also.[115a]

The separation of acetylene from gas mixtures containing ethylene, methane and hydrogen, is effected by washing with hexane at −80°C.[116] The dissolved gases are recovered in two stages, by warming the solution first to about −12°C. to remove methane and finally to about 87°C. to evolve ethylene and acetylene together with some hexane vapor. The latter mixture is then fractionated at about −70°C. under 2 atmospheres pressure to furnish pure components. A combination of solvent action (using water or acetone) and low temperature fractionation has also been proposed by Pyzel.[117]

Absorption in liquefied substances, e.g., ammonia or sulphur dioxide, which are gaseous at 15°C. and 1 atmosphere pressure and condensable at a temperature above −100°C., is recommended when a large proportion of hydrogen is present.[118]

To separate acetylene from coke oven gas, a mixture of ammonia and acetone[119] is employed at a temperature of −90°C.

Impurities in acetylene, including phosphine and hydrogen sulphide, may be removed by slow passage of the gas over granules prepared by vacuum drying a paste of bleaching powder, lime and a solution of calcium chloride.[120]

Solvents, such as acetone at about −20°C., are recommended as means of eliminating highly unsaturated hydrocarbons, e.g., diacetylene, from gaseous mixtures containing acetylene.[121] In the procedure, acetone is caused to flow countercurrent to a stream of gases (Fig. 54). If the temperature is maintained at −20°C. only diacetylene is said to be dissolved in the ketone. The latter is then withdrawn from the bottom of the scrubbing tower and warmed by heat exchange with gaseous hydrocarbons resulting from a pyrolytic operation. In this manner diacetylene is said to be removed from the acetone. The washing liquor may be further cooled and returned to the system. Additional liquids which may be employed, at temperatures between −80° and 150°C., are hydrocarbons, halogenated hydrocarbons or nitrobenzene.[122] Other procedures involve cooling the mixed gases to about −70°C.[123] or the preferential polymerization of diolefins, or other highly re-

Acetylene is occasionally an objectionable constituent of gases so that it is necessary to eliminate, more or less completely, relatively small amounts of it. This may be accomplished by hydrogenation at low temperature, e.g., 75-90°C., in the presence of a specially prepared catalyst containing nickel and alumina. Olefins are said to be unaffected by this treatment.[126] Another method involves hydrogenation at 250°C., using chromium or nickel compounds as contact agents.[127] Young[128] removes most of the acetylene in olefinic gas mixtures by washing with acetone. The residual acetylene is then completely eliminated by passage of the gases over specially reduced copper at 195°C. The spent catalyst is revivified by conducting air over it at 250°C. and reducing with hydrogen.

Porous fillers, prepared by coagulating a foam resulting from admixture of a cellulose solution and kieselguhr or peat, may be employed in the storing of acetylene.[129]

PRODUCTION OF DIOLEFIN HYDROCARBONS BY PYROLYSIS

Butadiene is an important product of the pyrolysis of many hydrocarbons, especially olefins and cyclohexane derivatives, and may be produced on an industrial scale by thermal decomposition of petroleum hydrocarbons. In addition, other conjugated diolefins are also formed. For example, piperylene (1-methylbutadiene) and also possibly isoprene have been found in the low-boiling liquids from the pyrolysis of kerosene by the Buizov method.[130] However, perhaps the most abundant diolefin (having 5 carbon atoms) is cyclopentadiene, as it has been found in the products obtained on cracking the lower paraffinic hydrocarbons[131] and also in the fraction boiling at 28-50°C. made by the thermal decomposition of kerosene.[132] Dedusenko[132a] determined (by interaction with maleic anhydride) that the portion of gasoline (made by pyrolytic operations at 760°C.) distilling between 20° and 60°C. contained 2.2 per cent of the diolefin. A larger proportion (3.62 per cent) was secured from the cut boiling at 35-40°C.

Butadiene is present in appreciable quantities in cracking gases, particularly those from vapor-phase operation at about 600°C. It is also, in all probability, an intermediate in the conversion of lower paraffins into aromatic hydrocarbons. Thus, the gaseous products obtained in a semi-industrial plant for the manufacture of benzol from Persian natural gas, by cracking at about 800°C., contained 1.08

per cent of butadiene.[133] Buizov[134] exposed cracking gases to an incandescent platinum wire to secure the same product. Cambron and Bayley[135] studied the aromatization of propane in a high-chromium alloy steel tube and obtained about 5 per cent of the diolefin when operating at 850°C. and at high rates of flow. Pyrolysis of a paraffin wax (melting at 53.2°C.) at temperatures above 650°C. was reported to furnish about 2.5 per cent of the conjugated olefin.[136] The conversion of ethylene into butadiene by cracking in a quartz tube filled with copper gauze and at a temperature of 700° to 750°C. has been studied by Vornov and Voronova.[137] Maximum butadiene recovery per pass was 2-4 per cent but this could be increased to above 10 per cent by 5 consecutive separations and recirculations of the ethylene. The optimum temperature was 750°C. and the use of diminished pressures did not affect the yield. According to Winkler and Häuber,[137a] ethylene admixed with acetylene and conducted at 600°C. through a reaction tube (made of manganese and copper) lined with tin furnishes the diolefin. Other catalysts which may be employed include zinc, aluminum, alloys of these, and brass. Butene-2 has been employed as raw material by Fedorov, Smirnova and Semenov,[138] who obtained a 21 per cent yield by passage of a 7:1 mixture of nitrogen and butene-2 through porcelain tubes at 700°C.; 18-24 per cent of the butene was decomposed per passage. Less conversion to butadiene was secured with zinc oxide, chromic oxide, silica gel, platinum, iron, copper or carbon as catalysts. With magnesium oxide the yields were 25-29 per cent. The chlorination and subsequent dechlorination of butene-2 over barium chloride at 360-400°C. has been investigated by Kazanskii and Rafilzon.[139]

Much better results may be obtained by pyrolysis of cyclohexane hydrocarbons in the presence of 1.5-4 volumes of steam at atmospheric pressure in the absence of catalysts, according to Zelinskii, Mikhailov and Arbuzov.[140] They report the following yields of butadiene, expressed in mole per cent of the hydrocarbon decomposed:—

Hydrocarbon	Temperature °C.	Yield of Butadiene
Cyclohexene	650	65.2
Δ^1-Methylcyclohexene	690	56.4
Cyclohexane	750	39.9
Methylcyclohexane	750	34.8
Ethylcyclohexane	750	41.2
Decalin	750	11.6

Pyrolysis of Δ^1-methylcyclohexene at 690°C. under similar conditions gave 35.3 per cent of isoprene as well as 75.1 per cent of ethylene. Thermic decomposition of chlorcyclohexene in vacuo by an osmium-tungsten filament results in the formation of chlorobutadiene and ethylene.[141] Cyclohexenenitrile may be similarly treated to obtain cyanobutadiene.

The catalytic decomposition of ethanol, according to the Lebedev[142] process, has been developed on an industrial scale in Russia for the production of butadiene, used as intermediate in the manufacture of synthetic rubber. Ethanol vapor is passed over a special catalyst (a mixture of alumina and zinc oxide) at temperatures of 420-470°C., whereby it is converted into butadiene to the extent of about 20 per cent. Numerous other products are simultaneously formed including pentene, hexene, piperylene, hexadiene, *p*-xylene, toluene, butanol, unsaturated alcohols,[143] aldehydes and ketones as well as methane, ethylene and butenes.[144] Two phenolic compounds, *o*-ethyl phenol and *o*-cresol, have been identified also.[145]

Substitution of *n*-propanol for ethanol results in the formation of about 6 per cent 1,3-dimethylbutadiene as well as some ethylene, propene, methyl-2-pentene and propionaldehyde.[146] When isopropanol is employed, and a catalyst consisting of 15-25 per cent zinc oxide and 75-85 per cent alumina, the main reaction product at 450°C. is said to be propene.[147] Increase of temperature to 580°C. is reported to cause dehydration and dehydrogenation, with a resulting formation of acetone. When 95 per cent of alumina and 5 per cent of zinc oxide was present, the formation of a diolefin, possibly 1,3-dimethylbutadiene-1,3, was observed. Also, it was stated that *sec*-butanol would react to furnish butene-2 at 450°C. with 25 per cent zinc oxide and 75 per cent alumina present. The mechanism of the reaction and the influence of various factors on the yield of butadiene have been described by Lebedev, Gorin and Khutoretzkaya,[148] and also by Smirnov.[149] Some of the liquid hydrocarbons, by-products in the Lebedev process, may be transformed into butadiene by thermal decomposition. Thus, the fraction boiling at 100-150°C. furnished a 15-20 per cent yield of the diolefin by pyrolysis at 550-600°C.[150]

Fractions rich in piperylene and amylene can be recovered from the condensate and the still residues of the catalytic decomposition of alcohols.[151] The condensate is rectified and the part boiling below 60°C. is collected, washed with ice water, treated with calcium chloride, again fractionated, and the portion boiling at 30-45°C. collected. The same procedure is followed with the residues. The fractions thus isolated are mixed and redistilled into cuts boiling at 35-37°C. and 37-40°C. These are treated with bromine, the resulting bromides separated and redistilled from zinc dust and granulated zinc. The products are piperylene (from 37-40°C. fraction) and methylethylethylene (amylene).

Butadiene may be prepared by dehydration of a mixture of 1,3-butene glycol over solid oxide dehydrating catalysts at temperatures of 160-500°C.[152] An 85-90 per cent yield is obtained by passage of a vaporized mixture of 80 per cent 1,3-butene glycol and 20 per cent water over a catalyst of trisodium phosphate containing 2 per cent free phosphoric acid at 270°C.[153] Cerium phosphate[154] has also been suggested as the contact agent. Instead of using a catalyst in the form of granules, a method of securing it rigidly to the heating surfaces with which the glycol is brought into contact is reported to give better results.[155] Chalmers[156] suggests dehydration of ethylene glycol monoethylether in the gas phase in the presence of metal oxide catalysts, such as alumina or thoria.

RECOVERY AND PURIFICATION OF BUTADIENE

Although distillation may be employed for separating and recovering gaseous hydrocarbons having 4 carbon atoms in their molecules, butadiene cannot be recovered in pure form from such a mixture by fractionation owing to the fact that its vapor pressure is very close to that of isobutene. The use of selective solvents for removing butadiene from other C_4 hydrocarbons has received considerable attention. Promising methods involve the formation of certain addition products, which can readily be resolved into their components by the action of heat.

Procedures for the extraction of butadiene from cracking gases have been reviewed by Markovich and Moor,[157] who recommend the use of selective solvents. It has been found by Moor and Dement'eva[158] that water and aqueous solutions of ethylene chlorohydrin, ethylene glycol, glycerol and acetone as well as of borax, silver nitrate and mercuric acetate were the best extracting media, though a considerable volume and uninterrupted circulation of the liquid were required.[159] However, it appears that butadiene is recovered from the contact gases of the Buizov process, operated industrially in Russia, by liquid absorbents such as kerosene, turpentine and tetralin. According to Smirnov,[160] the absorbent power of ethanol for the diolefin is less than that of kerosene. Absorption in alcohol is said to be effected most economically at a pressure of about 5 atmospheres.[161] Recovery of butadiene from the gaseous products of the Lebedev synthesis is also possible by adsorption in activated carbon, and more than 90 per cent efficiency is said to be attainable by this procedure.[162]

Butadiene from the catalytic treatment of ethanol by the Lebedev process contains considerable proportions of acetaldehyde as well as of ethers and various hydrocarbons. The aldehyde may be removed almost completely by washing with water.[163]

It has long been known that solutions of cuprous salts will dissolve relatively large amounts of gaseous butadiene. The solubility data of Joshua and Stanley[164] indicate that this diolefin is approximately eleven times as soluble as butene in an aqueous monoethanolamine solution of cuprous chloride. Thus, it was stated that a mixture of butadiene and butene-2 could be resolved by the use of cuprous chloride.[165] One cubic meter of an aqueous solution of the mixed mono- and diolefin is admixed with 200 kg. of cuprous chloride. An additional quantity of neutral aqueous solution of cuprous chloride is then incorporated at 10-15°C. and 1 atmosphere. When the butene-2 has been removed, the butadiene may be separated from the copper complex by heating the latter to 80°C. Van Peski[166] proposes a neutral aqueous solution of a cuprous salt and an alkali metal halide maintained under non-oxidizing conditions by having present (in the solution) reducing agents, such as hydroxylamine. This liquid medium extracts both butadiene and carbon monoxide. It has been shown by Brooks[167] that, under certain conditions, a solid insoluble addition compound is obtained by contacting butadiene with cuprous salt solutions or suspensions. The pure diolefin may be recovered by filtering the precipitate and heating it to about 60°C. According to Brooks this reaction is particularly applicable to the fraction of cracking gas containing hydrocarbons having 4 carbon atoms. The process is carried out by agitating the liquid hydrocarbons and a slurry of solid finely-divided cuprous chloride in water or an aqueous ammonium chloride solution in an autoclave at a temperature below 10°C. Mixing is continued for 1-2 hours after which monolefins are decanted from the butadiene double compound.

In cases where it is desired to eliminate, but not to recover, butadiene and similar compounds from mixtures of such hydrocarbons with monolefins, it is possible to condense the diolefin with various organic materials and to separate the adducts from unchanged monolefins. For example, the diolefins may be combined with benzoquinone, mesityl oxide, maleic anhydride or esters of maleic acid by heating to 100-150°C. The resulting products may be removed from accompanying monolefins by fractionation of the latter. Thus, the cyclic and acyclic diolefins present in hydrocarbon mixtures may be separated by condensation with *p*-quinones, such as α-naphthoquinone, at temperatures below 50°C. whereby addition compounds derived from anthraquinone are obtained. Since different types of cyclic dienes react at different rates, separation of these hydrocarbons from one another is possible by gradual addition of the quinone. For the condensation of acyclic diolefins, the temperature necessary is usually above 50°C.[167a]

It is known that diolefins will combine with sulphur dioxide to yield cyclic sulphones, which are resolved into their components by the action of heat. Perkins[168] suggests reacting hydrocarbon mixtures containing diolefins by heating to temperatures of less than 100°C. (best about 80°C.) under pressure with less than half their weight of sulphur dioxide. The diolefin sulphone is withdrawn from the reaction zone and crystallized.

Chapter 5

Production of Aromatic Hydrocarbons by Pyrolysis of Petroleum Hydrocarbons

Aromatic hydrocarbons are obtained by the pyrolysis of practically all other types of hydrocarbons at temperatures of 600-1100°C. On account of their high antiknock values, the lower aromatics, benzene, toluene and xylenes, are valuable constituents of cracked gasolines. The more recent developments in the production of aromatics by cracking have for their object the formation of optimum yields of light benzenoid hydrocarbons for blending with gasolines, and in this respect the lower paraffin hydrocarbons have received special attention since they constitute a cheap and abundant source of raw materials. Aromatization of paraffins and olefins would appear, therefore, to be a promising method for the better utilization of petroleum gases.

As pointed out previously (see Chapter 4), much higher temperatures may be employed in the laboratory for pyrolytic conversions than would be feasible in commercial operations. Furthermore, when the hydrocarbons undergoing treatment are liquids, e.g., kerosene distillates, the gas loss (i.e., the proportion of product obtained as butanes or other hydrocarbons of lower molecular weights) is often high, sometimes as much as 50 to 60 per cent of the charging stock. The application of pressure and the use of catalysts may reduce, at least to some extent, the destructive effects attendant upon the employment of high temperatures.

PRODUCTION OF AROMATIC HYDROCARBONS FROM LIQUID PETROLEUM FRACTIONS

According to Kofman,[1] cracking at 700°C. of the low-boiling (100° to 150°C.) hydrocarbons, from the pyrolysis of alcohol,[2] yields 5.8 per cent benzene, 19.5 per cent toluene and 18.5 per cent xylenes. Kanep[3] found that the proportion of aromatics decreased with increasing boiling range of the charging stock. Thus, he reported that, when cracked at 700°C., a petroleum fraction boiling up to 150°C. gave 20.9 per cent aromatics, that boiling at 150-210°C. yielded 15.6 per cent, while a third cut, distilling at 210-270°C., furnished 12 per cent. At still higher temperatures, e.g., a glowing platinum wire, Kogasin[4] was decomposed into light benzene hydrocarbons (20 per cent) and gaseous products (80 per cent).[5] The latter consisted mainly of unsaturated hydrocarbons.

Vapor-phase cracking of Surakhany paraffinic fuel oil at atmospheric pressure in an iron retort at 650-800°C. has been shown by Butkov, Rabinovich and Kolpenskaya[6] to yield substantial quantities of aromatic hydrocarbons. Within this temperature range the proportion of light products amounted to about 18 per cent. An increase in the cracking temperature raised the yield of benzene but toluene formation attained a maximum of 3.6 per cent and then decreased at higher temperatures. The naphthalene fraction of the products increased with the temperature of pyrolysis and was 2.7 per cent at 800°C. Cambron and Bayley[6a] point out that gasoline containing more than 25 per cent of aromatics is secured by the cracking of petroleum distillates, provided a condition of turbulent flow is maintained in the reaction zone.

[2] Pyrolysis of alcohol to butadiene, for the production of synthetic rubber, is discussed in Chapter 4.

[3] E. K. Kanep, *Materials on Cracking and Chemical Treatment of Products Obtained*, *Khimteoret (Leningrad)*, 1935, No. 2, 71; *Brit. Chem. Abs.* B, 1936, 484; *Chem. Abs.*, 1935, **29**, 5640.

[4] Kogasin is a mixture of hydrocarbons resulting from the reaction of carbon monoxide and hydrogen. See Chapter 52.

[5] F. Fischer, K. Peters and K. Winzer, *Brennstoff-Chem.*, 1935, **16**, 421; *Chem. Abs.*, 1936, **30**, 3991.

In the course of an intensive study of the vapor-phase cracking of various hydrocarbon materials in a KA2 steel tube, using steam as a diluent to minimize carbon production, Groll[7] found that the optimum temperature for aromatic formation was about 800°C. He obtained the following yields by pyrolysis of a refined gas oil, containing originally only small amounts of aromatic constituents.

Temperature °C.	750	800
Yield, gal. per bbl. of charge		
Olefins boiling below 75°C.	0.90	0.95
Benzene	3.03	3.87
Toluene	1.73	1.49
Xylenes and styrene	1.06	0.77
Trimethylbenzenes	1.32	0.52
Higher alkyl-benzenes	....	0.62
Naphthalene	....	12.4
Alkyl naphthalenes	....	8.53
Anthracene and phenanthrene	....	7.35
Alkyl anthracenes, etc.	....	3.82
Heavy tar residue	....	32.6

The influence of temperature on the composition of the light liquid reaction products is very clearly shown by Groll's results. The distillation curve of the liquids made by cracking at 600°C. does not show any plateaus characteristic of aromatic hydrocarbons. At 650°C. near the maximum gasoline yield, the plateaus for the lower aromatics first appear on the distillation curves. At this temperature, benzene, toluene and xylene are present in about equal amounts, though still mixed with much aliphatic hydrocarbons. At 700°C. the aromatics predominate in the light fractions with the yield of benzene exceeding that of toluene, and a smaller amount of xylene. A further increase of cracking temperature causes the gradual disappearance of the aliphatic hydrocarbons and fission of side chains from the alkylated aromatics. These changes are shown by the increasing sharpness of the breaks in the distillation curves and by the increase in the benzene plateau at the expense of those of toluene and xylene.

Aromatics may be obtained by the dehydrogenation of cyclohexane hydrocarbons in the presence of catalysts at relatively low temperatures. Petroleum fractions rich in cyclohexane hydrocarbons may be similarly dehydrogenated under these mild conditions without appreciably altering the other hydrocarbon constituents. Thus, Zelinskii and Shuikin[8] have effected almost complete dehydrogenation of cyclohexanes in fractions of Surakhany gasoline by passage of vapors of the latter together with hydrogen over catalysts of nickel on alumina, or platinum on activated charcoal, at 300°C. The condensates contained over 50 per cent by volume of aromatic hydrocarbons. Catalytic aromatization of Novo-Bogatinsk (Emba) gasoline in the presence of the same catalyst has been investigated also by Zelinskii and Shuikin.[9]

Pyhälä[10] investigated the naphthalene content of the light tar produced (in 50 per cent yield) by cracking Baku crude oil at 650-700°C. Variable proportions of naphthalene were obtained from this material by different methods of recovery, the largest being secured by fractionation in a long iron column whereby additional heating in the vapor phase resulted. Besides naphthalene, Pyhälä isolated two other solid hydrocarbons, melting at 80.5-81.0°C. and 82.5-83.1°C., respectively, which he believed to be labile isomers of naphthalene since they were converted into the latter by heat.

Pyrolysis of paraffin wax (Rangoon) at 450°C. furnishes liquid hydrocarbons which are partly aliphatic and partly cyclic, and analysis of these (by aniline point and refractive index) indicated they contained 1.6-1.7 benzene rings per molecule.[11] When operations are carried out the presence of hydrogen (at a pressure of 100 kg. per sq. cm.) the resulting products contain only 0.4-0.5 benzene rings per molecule. On the other hand, hydrogenation of the wax, using nickel on kieselguhr as a catalyst, prevented cyclization. It thus appears that the latter phenomenon may be controlled or entirely suppressed by choosing the proper conditions of pyrolysis.

PRODUCTION OF AROMATIC HYDROCARBONS FROM THE LOWER PARAFFINS

Because of their cheapness and availability in large amounts, the lower paraffin hydrocarbons have been extensively studied as raw materials for the production of the lower aromatic hydrocarbons. Methane is the preponderating constituent of most petroleum gases but pyrolysis of this hydrocarbon furnishes only small amounts of aromatic liquids even under the best conditions. The average yield of light aromatic oil at temperatures of 1000-1200°C. under optimum conditions of space velocity appears to be about 0.27 gal. per 1000 cu. ft. of methane.[12] The low conversions seem to be due to some extent to the marked inhibiting action of the hydrogen formed during aromatization. If some economic method of removing hydrogen can be found, the total conversion into benzene could be increased to perhaps 50-60 per cent of the methane supplied.[13] It is interesting to note that benzene constitutes about 80 per cent of the *light liquid* from the pyrolysis of methane.

The production of aromatic liquids from methane continues to be a subject of investigation although the reported yields are not superior to those originally procured by Fischer. Thus, Kafuku[14] obtained 3.5 kg. of oil per 1000 cu. ft. of natural gas (containing 94 per cent of methane) by pyrolysis in silica tubes at a temperature of 1000-1050°C. The light oil consisted of 95 per cent of benzene, while the heavy oil had about 50 per cent of naphthalene and 20 per cent of anthracene. Oda's[15] experiments on the decomposition of methane in quartz tubes showed oil yields of the same order as those obtained by Fischer. Dilution of methane with hydrogen or nitrogen greatly reduced these even when larger reaction tubes, higher temperatures and longer heating periods were employed. The formation of aromatic hydrocarbons from Japanese natural gases has also been investigated.[16] Optimum operating conditions with these gases, which are rich in methane, appeared to be a temperature of 1050-1100°C. and a contact time of 0.4-0.5 second. Single-pass operation furnished 87-113 g. of light oil per cubic meter of gas, while recycling gave increased yields but also furnished graphitic carbon and a gas containing 70-80 per cent of hydrogen. Fujio[17] reports 12 per cent of tar containing 23 per cent of benzol and 19 per cent of naphthalene from methane by pyrolysis in quartz or porcelain tubes at 1000-1150°C.

If the methane decomposition is limited to about 25 per cent and the temperature range kept within 1000° to 1200°C., then according to Smith, Grandone and Rall[17a] the optimum time of contact (Θ) in seconds is expressed by the formula

$$\log_{10}\Theta = \frac{19{,}525}{T} - 15.0967$$

The above relation is based upon the assumption that the pressure in the reaction zone is atmospheric.

The higher homologues of methane furnish much greater amounts of liquid hydrocarbons and at considerably low temperatures. Dustan, Hague and Wheeler[18] obtained the following yields of liquid aromatic hydrocarbons, calculated on gas input, by pyrolysis of the higher paraffins in silica tubes and at a gas flow of about 80 liters per hour per liter of reaction space.

TABLE 42.—*Single Stage Pyrolysis of Paraffin Hydrocarbons at Atmospheric Pressure*

Paraffin	Temp. °C.	% Conversion to Total Liquids	% Conversion to Gasoline below 170°C.	Yield of Light Oil below 170°C. Gallons per 1000 cu. ft.
Ethane	850	17.9	11.2	17.7
	900	21.9	10.6	16.0
Propane	850	23.1	11.7	25.6
Butane	800	20.4	12.9	38.5
	850	24.6	11.6	37.8
Pentane	850	26.8	11.9	—
Hexane	800	33.7	19.2	—
	850	33.8	19.0	—

Results obtained in silica tubes are usually not surpassed when the reaction zones are made of other substances, such as special alloy steels. Materials to be used in the construction of tubes for large production of aromatic hydrocarbons from petroleum gases should be heat-resisting, non-fragile, non-porous, should inhibit carbon deposition, and should catalyze benzene formation. Silica, porcelain, graphite, copper, aluminum, iron, nickel, fireclay and a number of alloys were tested by Dunstan and his co-workers on a laboratory scale but none proved entirely satisfactory. Two of the best alloys were Ferralloy (14 per cent aluminum, 86 per cent iron) and H.R.4 (26 per cent chromium, 0.3 per cent nickel, 1.5 per cent manganese, 0.9 per cent silicon, 0.15 per cent carbon and the remainder of iron). The former was found to be superior to silica in preventing carbon deposition and in favoring benzene production.

FIG. 55.—Effect of Turbulent Flow on Liquid Yields in Pyrolysis of Propane and *n*-Butane. (A. Cambron and C. H. Bayley)

The conversion of propane and *n*-butane into aromatic hydrocarbons by pyrolysis at atmospheric pressure in baffled quartz tubes has been investigated by Cambron and Bayley.[10] The advantage of employing conditions of turbulent flow is clearly shown in Fig. 55, in which the yields of liquids at various temperatures from a given tube are compared under conditions of turbulent and stream-line flow, respectively. Pyrolysis of propane in a baffled quartz tube at 950-1000°C. in a single stage operation furnished up to 20 lb. of total liquids and 12 lb. of light oil per 1000 cu. ft. of gas treated. By operating in 2 stages, with inter-stage separation of the liquids, these yields were increased to about 30 lb. of total oil and 20 lb. of light oil per 1000 cu. ft. Later, Cambron and Bayley[20] studied the conversion of propane into aromatic hydrocarbons by pyrolysis in baffled tubes of special heat-resisting alloys. Contrary to the experience of Groll,[21] these investigators observed that chromium-nickel steels of the KA2S type were unsuitable since they markedly catalyzed carbon deposition. However, a nickel-free chromium steel (containing 28 per cent of chromium) did not cause carbon deposition to any appreciable extent. Typical single pass experiments with tubes of the latter material at a temperature of 850°C. gave yields of total liquids aand light oil of 26 lb. and 19 lb., respectively, per 1000 cu. ft. of propane passed. Even better results were secured by recycling part of the exit gas and operating under slight pressure (up to 1 atmosphere). Under these conditions high rates of conversion could be obtained at temperatures as low as 800°C., 23 lb. of light oil together with 10 lb. of liquids boiling above 200°C. being produced per 1000 cu. ft. of propane put through. The composition of the liquids was determined by fractionation and chemical methods. The light oil contained 64 per cent benzene, 14 per cent toluene, 7.8 per cent styrene and small amounts of cyclopentadiene, xylenes and higher aromatics. The liquids boiling above 200°C. contained 25 per cent naphthalene, 12.5 per cent anthracene and smaller amounts of mono- and dimethyl naphthalenes, acenaphthene and phenanthrene.

Conversion of the lower paraffin hydrocarbons into liquid hydrocarbons can be effected in two stages, in the first of which the paraffin is pyrolyzed at high temperatures and low pressures to furnish a gaseous product rich in olefins, which is then subsequently polymerized at lower temperatures and high pressures. If aromatic hydrocarbons are desired, the polymerization step should be carried out at moderately low pressures, for example at 30-50 atmospheres and 600-650°C. Much higher yields of liquids are obtained by conducting polymerization at 200 atmospheres pressure and at lower temperatures, for example, 400°C. However, it was noted by Frolich and Wiezevich[22] that the use of the latter conditions causes a change in the chemical composition of the products from the aromatic type obtained at lower pressures to a decidedly non-aromatic material at the higher pressures.

The production of aromatic hydrocarbons from Persian natural gases in a semi-industrial plant has been described in some detail by Cadman.[23] The gases were first freed of hydrogen sulphide and were then conducted through a furnace and thence to a baffled reactor, which was not externally heated. After the heating section, the gas passed to a combined water-spray cooler and tar leg in which the gas temperature was reduced from 800-850°C. to about 90°C. and the bulk of the tar thus separated. After removal of naphthalene and tar fog, the gas was cooled in a series of film coolers and then led to the benzene recovery plant, which was of the usual oil absorption type.[24] A line diagram of the plant (without the desulphurization and refining sections) is shown in Fig. 56. The main line of research resolved itself into the testing of various furnace designs and materials from the viewpoints of satisfactory life at high temperatures, production of benzene and efficiency of heat transfer. Fireclay tubes, though resistant to temperature and non-catalytic as regards carbon formation, were unsuitable on account of poor heat transfer owing to the thickness of wall necessary for mechanical strength. Of the special steels tested, H.R.4 (containing 26 per cent of chromium and only 0.3 per cent of nickel) was the best but even this alloy became brittle on continued use with skin temperatures of 1000-1100°C. Calorized tubes were also tried but had a very short life under the operating conditions. The most satisfactory heating system consisted of a coil of straight lengths of tube with return bends connected by flanges, housed in a gas-fired furnace of the radiant heat type. Various other methods of heating were tried, including surface combustion and submerged flame heating, as well as tests in a recuperator furnace, but none of these proved very satisfactory. The reaction products consisted of carbon, a gas rich in olefins and liquids of an aromatic nature. In the portion of the latter boiling up to 200°C., there was a large fraction (boiling round 80°C.) consisting mainly of benzene together with some cyclohexene. Toluene was the predominating constituent in the cut boiling at 105-115°C. while styrene, *m*- and *p*-xylenes were present in the 135-150°C. fraction. Indene was isolated in the distillate boiling around 180°C. Naphthalene, anthracene and phenanthrene were readily isolated from the tar fraction boiling above 200°C., and the presence of chrysene was indicated.

FIG. 56.—Line Diagram of Plant for Production of Aromatic Hydrocarbons from Natural Gases. (W. H. Cadman)

Typical crude benzol yields by pyrolysis of various desulphurized Persian natural gases in H.R.4 reaction tubes at surface temperatures of the order of 1000-1050°C. and gas temperatures of 800-900°C. are given in Table 43. Pyrolysis experiments on a semi-technical scale in metal tubes and operating at a pressure of about 30 lbs. per sq. in. gave practically the same benzol yields as those obtained at atmospheric pressure. However, operation under slight pressure was advantageous since heat transfer was improved and throughput increased.

TABLE 43.—*Crude Benzol by Pyrolysis of Natural Gases*

Gas Pyrolyzed	Yield of Crude Benzol, Gallons per 1000 cu. ft.	% Composition of Benzol Benzene Fraction	Toluene Fraction	Styrene and Xylene Fraction
Low-Pressure stripped....	0.96	73.4	5.3	5.8
Low-Pressure unstripped..	1.46	69.1	6.4	7.1
Accumulator............	2.6	70.0	5.5	5.6

The refining of pyrolysis benzol has been briefly discussed by Cadman, who considers that the same general methods as those used for refining coal-tar benzene are also applicable. Sulphuric acid refining was satisfactory in that the refined product was stable and of good quality, although useful unsaturated material is wasted. Vapor-phase refining methods did not prove to be very successful but hydrogenation of such highly unsaturated fractions as the styrene fraction appears promising. Pyrolysis benzene is a good material for the testing of inhibitors.

PRODUCTION OF AROMATIC HYDROCARBONS FROM THE LOWER OLEFINS

Pyrolysis of the lower olefin hydrocarbons at temperatures of 700°C. or above leads to the production of considerable amounts of aromatic liquids. The proportions of such liquids from the lower olefins are considerably greater than those from the corresponding paraffin hydrocarbons, a fact readily explicable on the basis of the theory of aromatic formation, which is developed later. Typical yields of aromatic liquids from the lower olefins by single stage pyrolysis in quartz tubes at rates of flow of about 80 liters per hour per liter of reaction space are summarized[25] in Table 44. These results may be compared with the yields of aromatic liquids obtained by Groll[26] by pyrolysis of various olefin hydrocarbons at atmospheric pressure in KA2 steel tubes and at a rate of flow of 90 liters per hour per liter of tube space. (See Table 45.)

TABLE 44.—*Yield of Liquids by Pyrolysis of Olefins.*

The marked catalytic action of certain metals on hydrocarbon decompositions is well illustrated by the work of Hurd and Eilers[27] with ethylene, propene, isobutene, diisobutylene and pentene-2. In the presence of Monel metal, nickel and iron, the production of liquid hydrocarbons by pyrolysis of these olefins at temperatures of 600-700°C. was almost entirely suppressed while carbon formation was pronounced. In general, olefins are more susceptible to the catalytic influence of

these metals than are the corresponding paraffins. Hurd and Eilers found that Ascoloy (a chromium steel containing 24-30 per cent of chromium and 0.21-0.35 per cent of carbon) did not influence the development of carbon from the lower olefins at temperatures of 700°C., and the yields of aromatic liquids obtained with tubes of this metal were similar to those secured with silica and glass. Chromium, molybdenum and lead have been suggested also as contact agents.[28]

The effect of pressure on the production of aromatic hydrocarbons from olefins apparently cannot be deduced from the available kinetic data. However, Dunstan, Hague and Wheeler[29] found no increase in yield of aromatic liquids from ethylene at 600-700°C. when the pressure was raised from atmospheric to 150 lbs. per sq. in. At the higher pressure, however, the working temperature could be reduced by more than 100°C. without loss of yield but increasing the pressure in this temperature region appeared to accelerate the deposition of carbon. On the other hand, Wagner[30] recommends pressures of 500 to 1500 lb. per sq. in. and temperatures of 350-540°C.

PRODUCTION OF AROMATIC HYDROCARBONS FROM CYCLOPARAFFINS

It has long been known that cyclohexane hydrocarbons can be dehydrogenated in the presence of catalysts, such as platinum or nickel, to the corresponding aromatics. This method has been used for the preparation of the latter from petroleum fractions rich in cycloparaffins.[31] The equilibria involved in the transformation of the lower alkylcyclohexanes to the corresponding alkyl benzenes have been investigated by Vvedenskii, Vinnikova, Zharkova and Funduiler.[32] The rate of dehydrogenation of dimethylcyclohexane, at temperatures of 200° to 350°C. and in the presence of nickel or aluminum oxide catalysts, is only slightly greater than that of cyclohexane.[33] Very little methane is formed if the dimethyl derivative is pure.

In the absence of a catalyst, however, it is doubtful whether dehydrogenation is responsible for a large part of the aromatic materials from cyclohexanes on pyrolysis. In the purely thermal decomposition of cyclohexane at atmospheric pressure and at temperatures of about 650°C., the main reaction products appear to be butadiene and ethylene rather than benzene. In the case of cyclohexene,

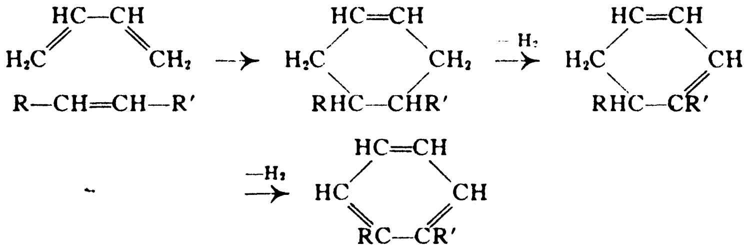
Schmidt[34] has shown that rupture of the ring occurs more readily than dehydrogenation. Also, this hydrocarbon does not form more aromatic hydrocarbons than any other olefin.[35] It seems likely, therefore, that the development of aromatics from cyclohexanes in purely thermal processes is the result of secondary decompositions of the ethylene and butadiene initially formed. The available information on the pyrolysis of cyclopentane hydrocarbons indicates that rupture of the ring is the main process and that aromatics are the result of secondary reactions of the olefins produced.

Dehydrogenation of hydroaromatic hydrocarbons in petroleum fractions is said to be effected at 300-500°C. in the presence of vanadium oxide on charcoal.[36] Difficulty reducible oxides or sulphides, such as those of nickel or molybdenum, are suggested also as catalysts,[37] as well as chromium-copper alloys.[38]

MECHANISM OF THE FORMATION OF AROMATIC HYDROCARBONS IN THE PYROLYSIS OF ALIPHATIC HYDROCARBONS

The exact mode of formation of aromatic liquids during the pyrolysis of aliphatic hydrocarbons is still the subject of much controversy. Butadiene is regarded by Wheeler and his co-workers[39] as the essential intermediate which may be produced by dehydrogenation of butene or by combined polymerization and dehydrogenation of ethylene. This diolefin, according to Wheeler's theory, combines with the lower olefins to form cyclohexenes which then dehydrogenate to benzenoid hydrocarbons according to the general scheme:—



In support of this mechanism it was found that equimolecular proportions of ethylene and butadiene react at comparatively low temperatures to give cyclohexene and the latter can be converted to the extent of 25 per cent into benzene at 700°C. Polynuclear aromatic hydrocarbons might be produced similarly by combination of butadiene and cyclohexene with subsequent dehydrogenation of the resulting partly hydrogenated naphthalenes. Dubois[40] also assigns an important role to ethylene as he found pyrogenation of this olefin for 1.5 and 6 minutes at 700°C. yielded almost exclusively aromatics. From these he isolated benzene, toluene, xylene, naphthalene and anthracene.

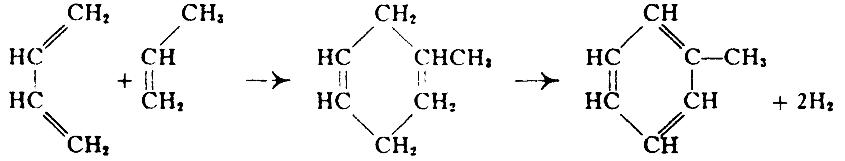
Groll[41] advanced a theory which appears to be a development of Berthelot's original concept of the intermediate formation of acetylene and subsequent polymerization of this hydrocarbon. According to Groll, divalent radicals of the type R—C=CH— and —HC=CH— ("nascent acetylene") result from demethanation of the lower olefins and these polymerize directly to aromatic hydrocarbons. It was considered nascent acetylene from demethanation of propene polymerizes to benzene rings more readily than it forms free acetylene. On the basis of this theory therefore, propene is an important intermediate in benzene production, and Groll believed that this was supported by the higher yields of aromatics from propene than from the other olefins. Hague and Wheeler[42] contest this conclusion and state that ethylene, under proper conditions, forms aromatic hydrocarbons to a greater extent than either propene or butene and that the ratio of toluene to benzene in the liquid products from propene is higher than for the other olefins. The high yield of toluene is due to interaction of butadiene and propene.



The assumption of the intermediate formation of divalent unsaturated radicals is not considered by Groll to be essential since acetylene should polymerize so smoothly under the cracking conditions necessary for aromatic production that it may well be an intermediate, though appearing to only a limited extent in the final products. It has been shown by Groll[43] that small quantities of acetylene are actually present in the pyrolytic products from both propane and propene at temperatures as low as 600-650°C.

Perhaps the most important objection which has been raised to Wheeler's theory is that cyclohexene, regarded by Wheeler as the immediate precursor of benzene, has a greater tendency to decompose into equimolecular proportions of ethylene and butadiene than to dehydrogenate thermally to benzene.[44] The yield of aromatic hydrocarbons obtained by cracking cyclohexene at 700°C. is about 46 per cent, of which about half is benzene. On the other hand, it has been shown by Wheeler and Wood, that substantial quantities of cyclohexene are produced by direct combination of butadiene and ethylene. It would seem therefore, that a quasi-equilibrium may exist between butadiene, ethylene and cyclohexene, according to the scheme,

$$C_2H_4 + C_4H_6 \rightleftharpoons C_6H_{10}(\longrightarrow C_6H_6 + 2H_2)$$

and that dehydrogenation of cyclohexene ultimately effects transformation of ethylene and butadiene into aromatics. If the conversion of cyclohexene into benzene is slow compared with the attainment of equilibrium between butadiene, ethylene and cyclohexene, such a scheme would serve to explain why pure cyclohexene decomposes to a considerable extent into ethylene and butadiene, while, on the other hand, pyrolysis of a mixture of ethylene and butadiene forms cyclohexene and aromatic hydrocarbons.

TECHNICAL PROCESSES FOR THE PRODUCTION OF AROMATIC HYDROCARBONS

The conversion of aliphatic hydrocarbons into aromatics involves heat treatment at temperatures of the order of 700°C. The factors influencing the yield of products include temperature, contact time, pressure and tube material or use of special catalysts. The available experimental data, however, appear to indicate that the yields are little affected by the pressure factor within certain limits, the main advantage being increased throughput of material. Many of the technical processes described are operated at about atmospheric pressure though in some cases inert diluents are employed to reduce the partial pressures of the reactants.

FIG. 57.—Development Plant for Production of Aromatic Hydrocarbons from Natural Gases. (W. H. Cadman)

The question of construction material is of prime importance since it is essential that the pyrolysis tubes should be mechanically strong, heat resistant, and nonporous and at the same time should not catalyze carbon formation. Tube walls should be as thin as possible, consistent with mechanical strength, otherwise heat transfer will be poor. This, of course, applies to the case of externally heated reactors which, in spite of some disadvantages, have been generally used. Special heat resisting alloys or tubes coated with heat resisting materials have been proposed. In this connection it is interesting to note that Wheeler[45] points out that materials having stable electronic structures, as shown by high values of electrical and thermal resistance, melting point, tensile strength, hardness and resistance to chemical action, do not catalyze decomposition of hydrocarbons into carbon and hydrogen. He suggests that alloy steels possessing these characteristics should be favored as structural materials in technical processes involving heat treatment of hydrocarbons. A number of such special steels have already been mentioned, the best of these being high chromium steels of low nickel content. However, Harnsberger[46] employed chrome-nickel alloy steels for the production of oil gas by pyrolysis of petroleum fractions at 700-760°C., the carbon deposit being periodically removed from the cracking zone by blowing with steam or air. According to Foster,[47] tubes of an alloy steel containing 25-30 per cent of chromium have been in use for three years in a vapor-phase cracking unit operating at a temperature of 870°C. It has been proposed to suppress still further carbon formation by coating tubes of heat resisting alloys with chromium or molybdenum.[48] Iron tubes covered with chromium or tin are recommended by Porter.[49] Steigerwald[50] reports that both chromium and graphite are useful contact materials for the conversion of natural gas into aromatic hydrocarbons at 800-1200°C.

A number of non-metallic refractory materials have been proposed as contact agents, as for example, chamotte plates or other non-metallic substances coated with silicon.[51] Another procedure is conducting gaseous hydrocarbons at a uniform velocity through a number of straight, unobstructed passages consisting of refractory materials such as chamotte, silicon or silicon carbide.[52] Chambers filled with checker bricks containing silicon carbide, zirconium or magnesite are recommended for effecting the conversion of olefins into aromatic hydrocarbons at elevated temperatures.[53]

Greenstreet[54] converts hydrocarbon gas mixtures into aromatic hydrocarbons by contacting the former at 600-1200°C. with catalysts which do not become coated with carbon. Examples are said to be copper, cobalt, manganese, chromium, molybdenum, tungsten, tin, aluminum, the alkali or alkaline earth metals, silicon, boron, and silica gel. Substances which resist high temperatures, such as the carbides, nitrides, silicides and borides of the above elements, or iron-aluminum alloys, silicon carbide or graphite may be employed. Lustrous carbon is used by Chesny[55] in the conversion of propane-containing gases into liquid hydrocarbons at 900-925°C. Other contact agents for the conversion of gaseous paraffins into benzene hydrocarbons by heat treatment in the absence of steam are the oxides of chromium, tungsten, vanadium or uranium.[56] Bauxite and fuller's earth have been suggested by Towne[57] and also the oxides of aluminum, nickel and zinc,[58] supported on silica gel, pumice, bauxite or activated carbon for the reforming of straight-run gasoline at 500-700°C.[59] Selenium vapors, at 650-950°C., are reported to aid in the transformation of aliphatics (e.g., ethane, propane and butane) into aromatics.[60]

The volatile, gaseous fractions, from the stabilization of natural gasoline, may be converted into aromatic hydrocarbons by mixing with 2-5 per cent of steam, preheating the mixture by contact with a hot mass of ferric oxide and then bringing it into contact with more ferric oxide at 538-593°C. Further steam is added to bring the total amount up to 15 per cent and the gases then contacted with an extended surface of metallic iron at 641-704°C.[61] In another process,[62] olefins are preheated to 300-800°F. and then raised to a higher temperature by admixture with hot gaseous combustion products. Afterwards they are passed into a reaction chamber filled with catalytic refractory material, such as fire brick coated with aluminum phosphate, alumina, ferric oxide or thoria. When the olefins contain admixed methane, regulation of the temperature can be effected so that only the unsaturated hydrocarbons are transformed into aromatics.[63] These are separated, and methane is recovered from the residual gas either by liquefaction or by treatment with copper oxide at 150°C. whereby hydrogen (from thermal decomposition of the hydrocarbons) is preferentially oxidized.

FIG. 58.—Semi-commercial Pyrolysis Plant for Aromatic Hydrocarbon Production. (W. H. Cadman)

Aromatics may be prepared from butane by maintaining it at a conversion temperature and pressure (470°C. and 3000 lbs. per sq. in., respectively) and adding successive small quantities of olefins.[64] Introduction of the latter should be so regulated that at no time do they constitute more than 5-10 per cent of the hydrocarbon present.

A two-stage process comprises first preheating refinery or natural gas to 550°C. and then conducting the products into a second heated, or soaking, zone (650-950°C.) where they are mingled with liquid gasoline or naphtha stock. By maintaining the mixture at the latter temperatures a high anti-knock gasoline is obtained.[65] Lawrence[66] separates still gases into several fractions, one of which is then heated to a temperature at which formation of unsaturated hydrocarbons occurs. The heated fraction, together with an untreated portion, is introduced into a reaction zone in which normally liquid aromatics are developed. The latter are separated and the unreacted gas is recycled. Frey[67] suggests that the volatile hydrocarbons be subjected to a temperature of 750-1200°F. and a pressure of 500-5000 lb. per sq. in. Afterwards the normally liquid products and methane are removed and the residual gases, under a pressure of 500 lb. per sq. in. are conducted through a reaction zone at 1250-1750°F.

MANUFACTURE OF BIPHENYL

The formation of biphenyl by condensation of two molecules of benzene (with elimination of hydrogen) is of technical importance since biphenyl can be used as a heat exchange medium. The preparation of biphenyl from benzene takes place over a wide temperature range, but in practice temperatures of 600-900°C. are usually employed. At 400-500°C. reaction is favored by increased pressures,[68] but commercial methods of manufacture are usually operated at too high temperatures for the application of pressures greater than a few atmospheres. It has been shown by Wibaut and his co-workers[69] that the yield of biphenyl at 420-440°C. under pressures of about 120 atmospheres is increased by catalysts such as hydrogen iodide, iodine and nickel.

At high temperatures, however, reaction is sufficiently rapid in the absence of catalysts for the industrial production, but carbon formation is apparently a troublesome feature and is catalyzed by some materials which are, therefore, to be avoided in continuous operation. Thus, García Banús and Guiteras[70] noted that the decomposition of benzene in the presence of a nichrome wire, heated electrically to 1020-1030°C., results in the deposition of graphite, which lowers the rate of biphenyl formation after a short time. It is reported that carbon formation at a temperature of 800°C. may be inhibited by coating the metal surfaces of the cracking tube with selenium, cobalt sulphide, cobalt, nickel chloride, copper sulphide, silicon, antimony, tin, molybdenum or its sulphides.[71] Williams[72] suggests adding about 0.1 per cent of sulphur, carbon disulphide, hydrogen sulphide or sulphur dioxide to benzene before subjecting it to pyrolysis.

A number of specific catalysts have been proposed for the production of biphenyl. One example of such is a neutral silicate of aluminum or magnesium, free from alkali metal compounds.[73] Drossbach and Roell[74] suggest an alkali metal oxide or oxides of thorium, cobalt, tungsten or aluminum. A catalyst consisting essentially of at least one difficultly reducible metal oxide, superficially coated with lustrous carbon, has also been recommended.[75] Instead of employing externally heated reaction chambers, Williams[76] decomposes benzene in a tubular, electrically heated element of graphite or silicon carbide at 650-950°C., the vapors to be pyrolyzed being preheated on the outer surface of the element. Or the volatilized benzene hydrocarbons are conducted through a heated steel tube under conditions of turbulent flow.[77]

FIG. 59.—Flow Diagram of Steam Boiler Unit Employing Dowtherm for Indirect Superheating and Reheating of Steam. (D. H. Killeffer)

In the process developed by Reilly,[78] benzene vapor (preheated to about 650°C.) is intimately mixed with about 2 parts by weight of steam (superheated to 1050-1100°C.). The resulting mixture, which is at a temperature of 800-950°C., is conducted through a steel reactor coated internally with a film of magnetic iron oxide. The yield of biphenyl from a single-stage operation may be as high as 30 per cent, this representing 90-95 per cent of the benzene reacting. Passage of benzene through molten inorganic salts at 750-850°C. is said to produce less carbonaceous by-products than when molten lead is used.[79]

FIG. 60.—Exterior Side View of Dowtherm Power Unit. (D. H. Killeffer)

Diaryl hydrocarbons are refined by treatment with an agent, such as concentrated sulphuric or phosphoric acid.[80]

On account of its thermal stability, biphenyl is finding considerable application as a heat-transfer medium, especially in the form of a low melting mixture with diphenyl ether (containing 26.5 per cent of biphenyl). This medium on continued exposure to air at temperatures of about 650°F. undergoes slight oxidation but in other respects is very stable.[81] Its use in a high-pressure steam boiler plant has been described by Killeffer.[82] In addition to diphenyl ether, naphthalene and diphenylamine or aniline may be incorporated with biphenyl.[83] The resulting composition should have a freezing point not higher than 6°C. It is interesting to note that biphenyl and diphenyl ether have been recommended as ingredients of a lubricant employed at high temperatures.[84]

Chapter 6

Action of Aluminum Chloride on Hydrocarbons

Aluminum chloride has long been known to exert a profound disintegrating and rearranging action on all types of hydrocarbons at relatively low temperatures but it is only within the last few years that the mechanism of such processes has received attention. Indications are that the chemical reactions involved comprise rupture of carbon chains, isomerization and polymerization, and that frequently all take place simultaneously. The practical applications of the action of aluminum chloride on hydrocarbons are (1) the production of gasoline from high boiling petroleum fractions, (2) the formation of higher boiling products, including hydrocarbons having lubricant properties, from olefin hydrocarbons, and (3) the synthesis of resinous materials from cracked distillates. The industrial future envisaged for gasoline made by cracking petroleum in the presence of aluminum chloride does not appear to have materialized. This is partly due to the fact that gasolines produced in this manner have relatively low antiknock values and are therefore not as satisfactory as those formed by thermal cracking operations.

Besides aluminum chloride, other anhydrous inorganic halides including boron trifluoride, tin tetrachloride or zinc chloride have been suggested both as catalysts for the preparation of gasoline and also for polymerizing unsaturated hydrocarbons. The action of such halides will be briefly described in this chapter, with particular attention to aluminum chloride from an industrial viewpoint.

PRODUCTION OF GASOLINE WITH ALUMINUM CHLORIDE

Processes employing aluminum chloride in cracking higher petroleum fractions to gasoline have usually been carried out at temperatures of about 300°C. and under sufficient pressure to avoid excessive volatilization of the chloride. Much information regarding the chemical composition of such gasolines is available from the researches of a number of Russian technologists. Thus, Zelinskii and Mikhlin[1] obtained a 48 per cent yield of gasoline, consisting of paraffin, naphthene and aromatic hydrocarbons, by cracking Emba crude petroleum with 10 per cent of aluminum chloride at atmospheric pressure. Treatment of Grozny paraffin at 130-140°C. was found to give 55 per cent of a colorless distillate of which the fraction boiling up to 150°C. contained only 3 to 4 per cent of aromatic hydrocarbons, corresponding to the dehydrogenated naphthenes, the remainder being paraffins. Gasoline (42 per cent yield) from cracking ceresin in the presence of aluminum chloride contained 2 per cent of aromatics and some naphthenes, while the light kerosene was mainly naphthenic. Zelinskii and Mikhlin noted that when only small proportions of the halide were used unsaturated hydrocarbons appeared in the cracked products.

The decomposition of a Rumanian kerosene by this means has been studied by

---

[1] N. D. Zelinskii and N. E. Mikhlin, *J. Applied Chem. (U.S.S.R.)*, 1933, 6, 16; *Foreign Petroleum Tech.*, 1933, 1, 8; *J. Inst. Pet. Tech.*, 1934, 20, 363A; *Chem. Abs.*, 1933, 27, 5176.

Candea, Kühn and Manughevici.[2] They found that reaction begins even in the cold, is more marked on heating and is very pronounced under moderate pressures. Tests carried out at temperatures up to 370°C. gave 24 per cent of light liquid and gaseous products boiling up to 150°C. The application of pressures of 10-40 atmospheres caused an increase to 40 per cent in the yield of light fractions. It was noted that the reaction took place at lower temperatures and pressures when a copper autoclave was employed.

From experiments on the cracking of kerosene, spindle, automobile and cylinder oils with 10 per cent of aluminum chloride, Borisov, Gaverdovskaya and Epifanskii[3] concluded that it was largely the naphthene hydrocarbons which were attacked. These were decomposed by the splitting off of side chains (afterwards appearing as paraffin hydrocarbons), by partial dehydrogenation with formation of aromatic hydrocarbons and by rupture of the ring system to yield paraffins and highly condensed hydrocarbons of the type of asphaltenes and carbenes. That aromatic hydrocarbons are present in the low-boiling fractions resulting from the action of the halide on petroleum distillates has also been shown by Dobryanskii and Zelenin.[4] A typical gasoline formed in this way was found to contain 2 per cent benzene, 5.4 per cent of toluene and 5.7 per cent of xylene, while the gas evolved was principally butane. Zudilov[5] obtained stable gasoline fractions by the action of 10 to 15 per cent of catalyst on the higher fractions of primary tar from sapropelite, the yields varying from 40 to 70 per cent.

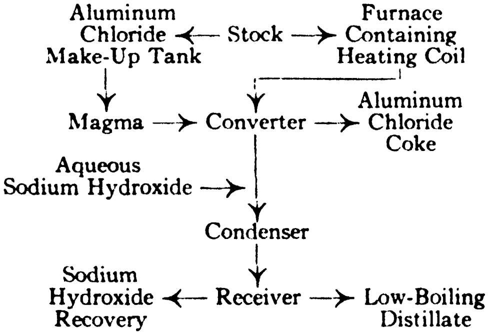

FIG. 61.—Flow Scheme for Cracking Petroleum Fractions with Aluminum Chloride Catalyst. (A. M. McAfee)

Instead of adding freshly prepared aluminum chloride to the petroleum fraction, the catalyst may be generated *in situ*. This was achieved by Galle[6] on adding the metal, previously activated by treatment with mercuric chloride, to petroleum and passing a current of dry hydrogen chloride through the mixture. Apparently a very active form of metallic chloride is produced, for by treating a petroleum fraction (boiling 155° to 300°C.) in this manner, an almost quantitative yield of gaso-

line is said to have been attained. The latter consisted of a mixture of paraffins, aromatics and naphthenes but no unsaturated hydrocarbons. The degree of amalgamation of the aluminum must be carefully controlled to give the optimum effect. In this connection it is interesting to note that high boiling hydrocarbons may be cracked by first halogenating at a temperature between 0° and 150°C. and then treating (at 100-150°C.) with aluminum which has previously been activated by immersion in a solution of a salt of a less electro-positive metal.[7]

Some details of a procedure for cracking high boiling petroleum fractions have been disclosed by McAfee.[8] The charging stock, (which should contain a high proportion of naphthenes), is heated to just below the temperature of incipient thermal decomposition, e.g., 315 to 400°C., and about 2 per cent of aluminum chloride is added in the form of a heated mixture containing 80 per cent of the catalyst and 20 per cent of oil. The mixture passes to a converter, which is not heated and in which an approximately constant oil level is maintained, and reaction is allowed to take place under a pressure of 75 to 300 lbs. per sq. in. The vapors leaving the reactor are sprayed with an aqueous solution of caustic soda prior to condensation. The coke which builds up in the reaction chamber may be removed periodically by cooling to below 100°C. and washing out with water or aqueous alkali. A somewhat similar cracking process has been described by Jenkins and Stratford,[9] who employ 2 to 10 per cent of an aluminum chloride-hydrocarbon catalyst and effect reaction under pressure and at a temperature (about 482°C.) at which conversion takes place almost instantaneously. To obviate corrosion in processes of this type, Stratford[10] subjects oils, which normally tend to liberate hydrogen chloride with these catalysts, to a preliminary treatment with the halide at a temperature substantially below that at which decomposition of the oil occurs but sufficiently high to effect release of the corrosive substances. An apparatus for refining petroleum utilizing metallic halides has been described by

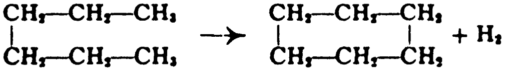
Carl.[11] This consists of a still fitted with a series of beaters so mounted that adjacent pairs inter-rotate in opposite directions, and thus furnish more intimate contact between the oil and catalyst.

Lelgemann[12] suggests cracking high boiling hydrocarbons at temperatures up to 370°C. in contact with 5 to 10 per cent of aluminum chloride, which is continuously reactivated by introducing charging stock containing about 0.3 per cent by weight of nitrosyl chloride. He also points out that both aluminum and iron halides may be employed in an amount not exceeding 12 per cent of the charge.[13]

ACTION OF ALUMINUM CHLORIDE ON PARAFFIN HYDROCARBONS

The action of aluminum chloride on the paraffin hydrocarbons is complex. Several different types of reaction occur simultaneously: In addition to isomerization, rupture of the carbon chain takes place with the production of a lower paraffin hydrocarbon and an unsaturated hydrocarbon fragment which is polymerized by, and probably combined with, the halide. Nenitzescu and Dragan[14] reported that freshly sublimed aluminum chloride caused *n*-hexane, at its boiling point, to partially decompose, forming a lower-boiling isomer, probably 2- or 3-methylpentane. In addition, simultaneous hydrogenation and dehydrogenation take place, producing pentane and cyclohexane in accordance with the following scheme:



$$\begin{array}{l} CH_2{-}CH_2{-}CH_3 \\ | \\ CH_2{-}CH_2{-}CH_3 \end{array} \longrightarrow \begin{array}{l} CH_2{-}CH_2{-}CH_2 \\ |\qquad\qquad\quad | \\ CH_2{-}CH_2{-}CH_2 \end{array} + H_2$$

With *n*-heptane this catalyst causes the formation of fractions boiling both lower and higher than heptane. The low boiling fractions are apparently paraffins formed by splitting of the hydrocarbon chain, while the high boiling fractions consist of mono- and bicyclic naphthenes. Moist aluminum chloride yields a considerably increased quantity of gases (cleavage products), the proportion of the latter being to some extent determined by the amount of water present. A hydrogenation action of aluminum chloride is strongly evidenced with alkyl chlorides. Under these conditions a vigorous action occurs by which the alkyl chloride is reduced to the corresponding hydrocarbon at the expense of hydrogen from the heptane, which in turn is largely converted to higher boiling cycloparaffins, and only slightly to the lower paraffins.

A similar investigation with *n*-hexane was made by Calingaert and Beatty,[15] who modified the procedure in that the low-boiling reaction products were continuously withdrawn and subsequently identified. Tarry polymerization products were also separated but not studied in detail. The yields of the various hydrocarbons isolated are given (on a percentage basis) in Table 46.

It is suggested that branched-chain heptanes may result from condensation of lower-boiling hydrocarbons formed in the reaction. *n*-Heptane refluxed with aluminum chloride yielded three hexanes, together with at least three and probably five of the eight branched-chain heptanes, these hydrocarbons totaling about 5 to 6 per cent of the reacted *n*-heptane.

FIG. 63.—Drawing of Apparatus for Treating Petroleum Oils with Aluminum Chloride. (B. E. Carl)

The work of Grosse and Ipatieff[17] on the reaction between paraffins and aromatic hydrocarbons in the presence of anhydrous inorganic halides would seem to shed considerable light on the mechanism of the decomposition of paraffin hydrocarbons under the influence of such catalysts. By passing dry hydrogen chloride through a mixture of benzene, 2,2,4-trimethylpentane and aluminum chloride at

[17] A. V. Grosse and V. N. Ipatieff, *J.A.C.S.*, 1935, 57, 2415; *Chem. Abs.*, 1936, 30, 1751; *J. Inst. Pet. Tech.*, 1936, 22, 86A.

25 to 50°C. (or zirconium tetrachloride at 50 to 75°C.), these investigators obtained isobutane and a mixture of mono- and dibutylbenzenes. No reaction occurred in the presence of magnesium chloride or of nickel-promoted boron trifluoride. It is reasonable to assume, therefore, that aluminum chloride and zirconium tetrachloride decompose paraffins with the production of a lower paraffin and the complementary olefin, which, in the presence of aromatic hydrocarbons, is immediately converted into an alkylated aromatic hydrocarbon.

As a result of investigations involving the action of aluminum chloride on *n*-butane, *n*-hexane, *n*-heptane and 2,2,4-trimethylpentane in the presence of dry hydrogen chloride, Ipatieff and Grosse[18] proposed the following general mechanism of the reaction, which they termed an "auto-destructive alkylation." The initial reaction was considered to result in the rupture of a carbon-carbon bond and the formation of a paraffin and an olefin, either directly or through free radicals, according to the equation:

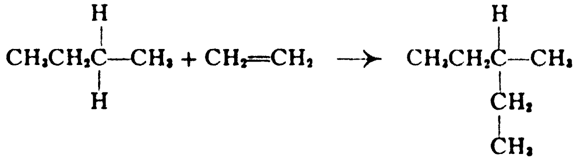
$$C_nH_{2n+2} \longrightarrow \underset{\textit{lower paraffin}}{C_{n-x}H_{2(n-x)+2}} + \underset{\textit{olefin}}{C_xH_{2x}} \qquad (1)$$

The olefin from reaction (1) can directly combine with a paraffin under the influence of a Friedel-Crafts catalyst giving a higher paraffin by alkylation.

$$C_nH_{2n+2} + C_xH_{2x} \longrightarrow \underset{\textit{higher paraffin}}{C_{n+x}H_{2(n+x)+2}} \qquad (2)$$

This is the antithesis of reaction (1) and probably accounts for the isomerization of paraffin hydrocarbons under the influence of these catalysts. Thus, the isomerization of *n*-hexane can be formulated in the following manner:

$$\underset{\textit{n-hexane}}{CH_3CH_2CH_2CH_2CH_2CH_3} \longrightarrow \underset{\textit{n-butane}}{CH_3CH_2CH_2CH_3} + \underset{\textit{ethylene}}{CH_2{=}CH_2}$$



$$CH_3CH_2\overset{H}{\underset{H}{\overset{|}{\underset{|}{C}}}}{-}CH_3 + CH_2{=}CH_2 \longrightarrow CH_3CH_2\overset{H}{\underset{\substack{|\\ CH_2\\ |\\ CH_3}}{\overset{|}{C}}}{-}CH_3$$

n-butane *ethylene* *isohexane*

The olefin resulting from the first reaction may, instead of combining with a paraffin molecule, undergo polymerization to yield a higher olefin which can in turn react either with a paraffin molecule to yield a higher paraffin or with the metallic halide to form a complex (lower layer).[19]

The overall effect of the action of aluminum chloride on the paraffins is embraced in the following general equation:

$$zC_nH_{2n+2} \longrightarrow aC_{x_1}H_{2x_1+2} + bC_{x_2}H_{2x_2+2} + cC_{x_3}H_{2x_3+2} + \dots\dots \qquad (3)$$

$$\text{where } z{\cdot}n = ax_1 + bx_2 + cx_3 + \dots\dots$$

Ipatieff and Grosse found that the presence of dry hydrogen chloride was essential and in the absence of the latter no reaction took place between the Friedel-Crafts agent and paraffins except at higher temperatures (about 150-200°C.). In the case of *n*-butane, no appreciable action took place below 100°C. even in the presence of hydrogen chloride. However, at 175°C. *n*-butane was converted into propane, ethane and methane and also partly isomerized to isobutane. Treatment of *n*-hexane for 3 hours at its boiling point with aluminum chloride and a small amount of hydrogen chloride converted this hydrocarbon (to the extent of 20 to 25 per cent) into a mixture of higher- and lower-boiling paraffins including isobutane and isomeric hexanes. Decomposition of the resultant sludge with water yielded an unsaturated oil. In a similar way, *n*-heptane at its boiling point furnished, after 3 hours, about 35 to 40 per cent of paraffin hydrocarbons consisting of substances of both lower and higher boiling points than the original hydrocarbon, and unsaturated oils recovered from the sludge. In the case of 2,2,4-trimethylpentane, the reaction with the catalyst in the presence of a trace of hydrogen chloride took place even at room temperature, and after 3 to 4 hours at 25-50°C. about 90 per cent of this octane was converted into lower and higher boiling paraffin hydrocarbons. In addition, a small amount of unsaturated oil was recovered by decomposing the aluminum chloride sludge with water. Of special interest in this work was the production of relatively large amounts of isobutane from the various paraffin hydrocarbons.

Glasebrook, Phillips and Lovell[20] obtained analogous results with aluminum chloride and *n*-pentane. These investigators also noticed that this promoter did not react detectably in completely anhydrous media, even over considerable periods. Addition of small amounts of water, hydrated aluminum chloride, or alkyl chlorides initiated disintegration. However, when aluminum oxide was added to an anhydrous aluminum chloride-*n*-pentane mixture, no reaction resulted, thus indicating that hydrogen chloride was the activating substance. (Hydrogen bromide served equally well in this capacity.) The principal products of the decomposition are isopentane and butanes, the quantity of the latter increasing linearly with reaction time. The isopentane concentration, however, increases rapidly toward a maximum value, then declines slowly with continued contact. Certain undefined, saturated high-boiling products and an insoluble, unsaturated polymer were also isolated but were not identified.

These workers found that aluminum bromide, on the other hand, although giving rise to the same products, did not require the addition of an initiating agent, and even under anhydrous conditions reacted readily and considerably more vigorously than did the chloride. A reaction mixture containing 1.52 mole per cent of aluminum bromide dissolved in the pentane underwent the same conversion in one half the time as did a mixture containing 17.4 mole per cent of aluminum chloride (promoted by 0.2 per cent of water per mole of aluminum chloride).

The decomposition of octadecane and hexatriacontane by anhydrous aluminum chloride has been discussed by Bauer and Toma.[21] The light liquid products boiling up to 175°C. appeared to be entirely saturated and probably paraffinic, since they were not attacked by strong sulphuric acid and had iodine numbers of practically zero. Octadecane yielded 60 per cent of liquids boiling up to 175°C., 13 per cent of a gas (85 per cent of which was lower paraffins), and a residue of carbonaceous material. Under similar conditions hexatriacontane furnished 33 per

[20] A. L. Glasebrook, N. E. Phillips and W. G. Lovell, *J.A.C.S.*, 1936, 58, 1944; *Chem. Abs.*, 1936, 30, 8145; *J. Inst. Pet. Tech.*, 1937, 23, 22A; *Brit. Chem. Abs.* A, 1936, 1485.

[21] K. H. Bauer and V. Toma, *Ber.*, 1934, 67, 1135; *Chem. Abs.*, 1934, 28, 5804; *Brit. Chem. Abs.* A, 1934, 864.

cent of volatile liquids, 30 per cent of heavy oils boiling up to above 450°C., 24 per cent of carbonaceous residue and 13 per cent of gas.[22]

It appears from the work of Petrov, Meshcheryakov and Andreev[23] that anhydrous zinc chloride, though much less active than aluminum chloride, is capable of causing the isomerization of paraffins at fairly high temperatures. Thus, with this chloride, *n*-heptane was found to isomerize to the extent of 20 to 25 per cent in 6 hours at 300 to 400°C. under 50 atmospheres of hydrogen.

ACTION OF ALUMINUM CHLORIDE ON UNSATURATED HYDROCARBONS

The mechanism of the vigorous action between Friedel-Crafts agents and olefins has not yet been elucidated. Polymerization is perhaps the most important reaction, especially at low temperatures, but other transformations, such as isomerization and splitting off of lower paraffin hydrocarbons, also take place. In general the products obtained from olefins at low temperatures consist of a polymerized free oil and a metal halide-hydrocarbon complex, from which the combined oil can be liberated by decomposition with water. At higher temperatures the free oil invariably contains large proportions of paraffin hydrocarbons in the lower boiling fractions, and the metal-hydrocarbon complex tends to coke.

The polymerization of ethylene by means of a suspension of aluminum chloride in pentane at 125 to 150°C. and under a pressure of 70 to 250 kilograms per sq. cm. has been examined by Waterman and Tulleners.[24] The combined oil, representing about 10 per cent of the total oil yield, was liberated from the pasty complex and separated into fractions, each of which was subjected to hydrogenation. From the results it was concluded that this oil is highly unsaturated and contains cyclic hydrocarbons, the average number of rings per molecule increasing from 1.2 in the lower boiling fractions to 2.5 in the viscous higher fractions. The free oil consisted almost entirely of paraffin hydrocarbons (especially in the lighter fractions), with an increasing proportion of saturated cyclic hydrocarbons in the high-boiling portions.

From the physical properties of the lower boiling substances Waterman and Tulleners deemed it probable that considerable proportions of branched-chain paraffins were present. This is supported by the work of Bowen and Nash,[25] who examined the liquid boiling up to 200°C. (51 per cent by volume of the crude product) formed by polymerizing ethylene with aluminum chloride at 150 to 160°C. under a pressure of 45 to 55 atmospheres. The octane number of this ethylene-polymer liquid averaged about 77 and was thus considerably higher than a Pennsylvania straight-run motor fuel. This fact in conjunction with other physical characteristics indicated the presence of large proportions of branched-chain paraffins.

In view of the experiments involving paraffins and olefins, Ipatieff and Grosse[26] believe that reactions using low-boiling paraffins as "inert solvents" might not give a true picture of the condensation of ethylene alone. Studies were therefore carried out using pure ethylene and pure aluminum chloride in glass-lined autoclaves. These workers also point out that the pure, dry substances do not react, even under pressures up to 50 atmospheres at 10° to 50°C., but that traces of hydrogen chloride (or moisture) must be present. Under the latter conditions, a maximum of about 10 molecules of ethylene are condensed by 1 molecule of the catalyst (thus 100 grams of catalyst polymerized 193 grams of ethylene). Investigation of the polymer resulting from treatment of ethylene at 25° to 30°C. under 20 atmospheres pressure showed considerable chemical difference between the free upper layer and the combined lower layer. The former was almost wholly paraffinic, though the reactivity toward potassium permanganate solution indicated the presence of some unsaturates and possibly naphthenes. The lower layer, however, after decomposition with ice water, was completely soluble in 96 per cent sulphuric acid, suggesting that it was entirely composed of unsaturates. Molecular weight and bromine number determinations gave an average value of two to three double bonds per molecule. Hydrogenation of certain fractions (boiling between 175° and 212°C. and 264° to 292°C.) yielded naphthenes, and hence, the original fractions were considered to have been cyclic unsaturated hydrocarbons of the terpene type. The polymerization mechanism was believed to begin as follows:

---

[22] H. Gault and R. Sigwalt (*Ann. combustibles liquides*, 1927, **2**, 309, 543; *Chem. Abs.*, 1928, **22**, 379) obtained chiefly butane and a little propane in the gaseous products of the cracking of hexadecane in the liquid phase in the presence of aluminum chloride.

$$H_2C{=}CH_2 + HCl \xrightarrow{(AlCl_3)} H_3CCH_2Cl$$

$$H_3CCH_2Cl + H_2C{=}CH_2 \xrightarrow{(AlCl_3)} CH_3CH_2CH{=}CH_2 + HCl$$

Polymerization of a mixture of lower gaseous olefins (85 per cent total unsaturates) by aluminum chloride has been studied by Potolovskii and Atal'yan.[27] The products obtained at room temperature after ten days contained 45 to 50 per cent of gasoline and kerosene hydrocarbons and 50 to 55 per cent of heavier oil. The latter had a lower specific gravity and a higher viscosity index than corresponding natural oil fractions. The residue obtained on vacuum distillation was a drying oil formed by the polymerization of diolefins with olefins and to some extent with benzene. When polymerization was carried out at 70°C., the resulting hydrocarbons had a lower average boiling point.

The preparation of gasoline from unsaturated hydrocarbon gases by passage at 350° to 700°F. and 600 to 1500 lbs. per sq. in. pressure over catalysts of the metallic halide type, including also iron chloride and titanium chloride, has been described by Wagner.[28]

The lower olefins having a branched-chain structure, such as isobutene and trimethylethylene, are particularly susceptible to polymerization under the influence of Friedel-Crafts condensing agents. The former reacts violently even at temperatures as low as −80°C. and the products have a very high mean molecular weight. According to Waterman, Over and Tulleners,[29] such low temperature polymers have a partly cyclic structure and are mainly saturated. High molecular weight substances having a more or less cyclic character have also been obtained by polymerization of isopropylethylene, *asym*-methylethylethylene and trimethylethylene by aluminum chloride at −80°C.[30] At higher temperatures (85° and 200°C.) yields of substances having partly cyclic structures (i.e., naphthenic hydrocarbons) have been obtained.[31] Iso-olefins have been reacted at temperatures as low as —80°C. with catalysts such as boron trifluoride.[32] Thus the action of gaseous or solid volatile halides of elements of Groups 2, 5, 6 and 8 (e.g. beryllium, arsenic, uranium, iron or osmium chlorides or fluorides) on liquid isobutene at temperatures above —10°C. produces high molecular weight polymers. The liquid volatile halides such as tin tetrachloride, titanium tetrachloride or antimony pentafluoride may also be used, as well as aluminum chloride (formed *in situ* by the action of hydrogen chloride on aluminum chips, previously activated with mercuric chloride) at temperatures not above 50°C.[33]

The straight-chain olefins do not react as vigorously as the branched isomers. Polymerization of pentene-2 with aluminum chloride as a catalyst is slow at —80°C. but more rapid at 0°C. From pentene-2 and this catalyst at 0°C. Waterman, Leendertse and Klazinga[34] obtained a free oil (constituting about 80 per cent of the total reaction resultants) which had very low bromine absorption values and appeared to be a mixture of aliphatic and naphthenic hydrocarbons.

No appreciable reaction of cyclohexene with aluminum chloride has been found by Waterman, Leendertse and ter Poorten[35] at temperatures below 0°C., and even at 40°C. polymerization was still very slow. However, it was possible to condense cyclohexene quite rapidly at 70°C. to high molecular weight polymers. Approximately equal proportions of free and combined oils resulted. The latter liberated from the complex, was more unsaturated than the free oil, which had a very low bromine number. Hydrogenated fractions of both the free and combined oils had specific refractivities in close agreement with those calculated for cyclohexyl hydrocarbons of the same molecular weight. In the presence of hydrogen chloride, however, cyclohexene was found to react vigorously under the influence of aluminum chloride catalysis even at —78°C. to furnish a mixture of monochlorocyclohexane and monochloropolycyclohexyl compounds, the latter being formed by the addition of hydrogen chloride to the cyclohexene polymers.

Action of Aluminum Chloride on Cycloparaffins

The action of aluminum chloride on cyclohexane, alone or in the presence of other substances, has received considerable study. In order to explain the reaction between this hydrocarbon and acetyl chloride in the presence of Friedel-Crafts agents, Zelinskii and Tarasova[36] considered that the initial change was one of dehydrogenation in which cyclohexane behaves as a mixture of *cis*- and *trans*-isomers. The *cis*-form furnishes cyclohexene (converted to tetrahydroacetophenone by acetyl chloride) while dehydrogenation of the *trans*-form was thought to proceed through a dicyclic system, which could undergo fission to yield unsaturated radicals, as summarized below:

The two ketones produced, namely cyclohexyl methylketone and 2-acetyl-1-methylcyclopentane, were considered to be derived from the two unsaturated residues by direct combination of acetyl chloride and hydrogen with elimination of hydrogen chloride. To account for the production of 1-methyl-2-acetylcyclopentane from cyclohexane and acetyl chloride in the presence of aluminum chloride, Nenitzescu and Cantuniari[37] assumed that cyclohexane is first isomerized to methylcyclopentane, which then undergoes dehydrogenation to methylcyclopentene, the latter subsequently reacting with acetyl chloride. Later, Nenitzescu and Isacescu[38] found that, in the absence of a hydrogen acceptor, the main reaction between aluminum chloride and cyclohexane was isomerization to methylcyclopentane. With substances readily reducible by hydrogen (such as arsenic, antimony, or phosphorus trichloride, sulphur chlorides and sulphuryl chloride), the predominant effect was a dehydrogenating condensation, which occurred according to the equations:

$$2C_6H_{12} \longrightarrow C_{12}H_{22} + H_2$$
$$3C_6H_{12} \longrightarrow C_{18}H_{32} + 2H_2$$

Thus, by the action of aluminum chloride and arsenic trichloride on cyclohexane at 65-70°C., the hydrocarbon $C_{12}H_{22}$, melting at 46°C., was produced.

The action of aluminum chloride on cyclohexane in the presence of hydrogen chloride at a temperature of 150°C. has been investigated by Ipatieff and Komarewsky,[39] and under these conditions the hydrocarbon suffered profound change. The resultant consisted of a small percentage of gas, containing a large proportion of isobutane, and a mixture of liquid hydrocarbons in which methylcyclopentane, 1,3-dimethylcyclohexane, dimethyldicyclopentyl (melting at 46-47°C. and identical with the $C_{12}H_{22}$ hydrocarbon obtained by Nenitzescu and his collaborators) and dicyclohexyl. Ipatieff and Komarewsky believed that dimethylcyclohexane was formed by isomerization of ethylcyclohexane. The latter resulted from ethylation of cyclohexane by ethylene (a decomposition product of the original hydrocarbon). The $C_{12}H_{22}$ hydrocarbons were probably formed by dehydrogenation and condensation, and the lower paraffins by destructive hydrogenation. The whole reaction scheme may be written:

---

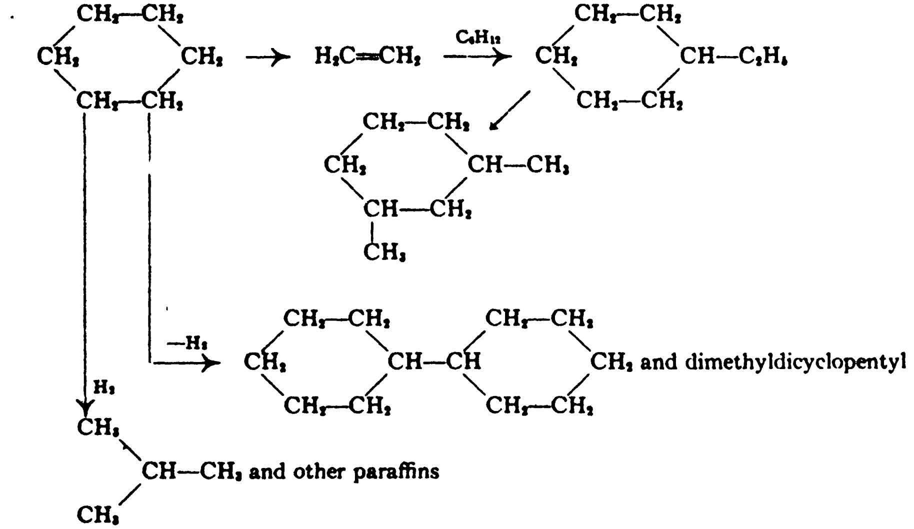
[39] V. N. Ipatieff and V. I. Komarewsky, *J.A.C.S.*, 1934, 56, 1926; *Chem. Abs.*, 1934, 28, 6704; *Brit. Chem. Abs.* A, 1935, 1209.



From a study of the decomposition of a number of simple cyclohexane hydrocarbons by heating at 120 to 130°C. with 10 per cent finely ground aluminum chloride, Turova-Polyak[40] has concluded that these monocyclic compounds can be isomerized to cyclopentane rings. Thus, under the conditions stated above methylcyclohexane gave rise to cyclohexanes, cyclopentanes and paraffins in the ratio 78.6:20.4:1.0 respectively. Under similar treatment dimethylcyclohexane yielded fractions in which the percentages of cyclohexanes varied from 84.6 to 68.9, the cyclopentanes from 19.4 to 11.5 per cent, and the paraffins from 11.7 to 4.0 per cent. Aluminum chloride also was found to cause isomerization of ethylcyclohexane to 1,3-dimethylcyclohexane.

By decomposition of decahydronaphthalene with 10 per cent of aluminum chloride at 175 to 210°C., Zelinskii and Turova-Polyak[41] obtained a mixture of liquid hydrocarbons boiling between 80 and 180°C. but practically no gas was evolved. In this instance the reaction product consisted almost entirely of cyclohexane and cyclopentane hydrocarbons and dicyclic hydrocarbons of the type of dimethyldicyclopentane, with only small amounts of paraffins. It was concluded that the *cis*-form of decalin was first isomerized to the *trans*-isomer, which in turn was converted into dimethyldicyclopentyl.

ACTION OF ALUMINUM CHLORIDE ON AROMATIC HYDROCARBONS

In the products of the action of aluminum chloride on benzene, several hydrocarbons have been identified, including biphenyl, toluene and ethylbenzene.[42] Gustavson[43] obtained 1-methyl-3-phenylcyclopentane and diphenylcyclohexane by treating benzene in this manner at room temperature for several weeks. Later, Wertyporoch and Sagel[44] secured phenylcyclohexane, biphenyl, *o*-diphenylcyclohexane and a mixture of phenylated methylcyclopentanes and cyclohexanes by the prolonged action of aluminum bromide on benzene at 18°C. In addition, phenolic substances were also formed, probably as the result of the intervention of oxygen or water. By heating benzene at 125°C., in an autoclave (in the absence of air), with 10 per cent of aluminum chloride and small amounts of dry hydrogen chloride, Ipatieff and Komarewsky[45] obtained 1.7 per cent of ethylbenzene and 0.8 per cent of biphenyl, calculated on the benzene charged. The presence of ethylbenzene was thought to be due to the direct ethylation of benzene by ethylene released by destructive hydrogenation of the benzene. This mechanism was supported by the fact that unsaturated polymers of ethylene were recovered from the sludge.

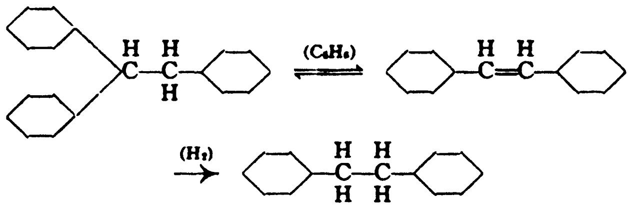
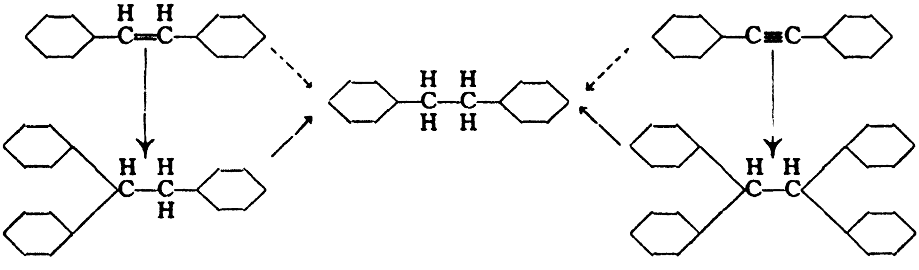
[41] N. D. Zelinskii and M. B. Turova-Polyak, *J. Appl. Chem.* (*U.S.S.R.*), 1934, 7, 753; *Chem. Abs.*, 1935, 29, 2528; *Brit. Chem. Abs.* A, 1935, 204.

[42] In the presence of aluminum chloride, the exchange reaction between hydrogen and "heavy hydrogen," or deuterium, in benzene proceeds almost quantitatively, A. Klit and A. Langseth (*Z. physik. Chem.*, 1936, A176, 65; *Chem. Abs.*, 1936, 30, 5091; *Brit. Chem. Abs.* A, 1936, 714) have reported.

Alexander and Fuson[46] observed that ethylenic bonds between phenyl groups, as in stilbene, are hydrogenated in the presence of aluminum chloride and benzene. It is believed that phenylation (i.e., to produce triphenylethane) competes with hydrogenation (leading to the formation of bibenzyl). The reaction producing bibenzyl is, however, irreversible, while that yielding triphenylethane is reversible:



Thus, the production of bibenzyl in the presence of benzene and aluminum chloride is a general phenomenon for the acetylene and ethylene derivatives which bear one or more phenyl groups on each carbon atom. This general statement is represented in the following schematic reaction:



A product containing up to 98 per cent of the theoretical amount of deuterium was prepared by the interaction of deuterium chloride and benzene in the presence of the catalyst. The properties compare with those of hydrogen benzene as follows:

Benzene	Density	Melting Point °C.
C_6H_6	0.878	5.5
C_6D_6	0.9483	6.64

When exchange of hydrogen and deuterium takes place, the deuterium atoms are distributed between the benzene nuclei in such a way that the product is a mixture of the possible isomeric deuteriobenzenes in such proportions as correspond with the laws of probability.

Rearrangement and fission of side chains appears to be the predominating result of the action of the metal halide on the alkylbenzenes, although some dehydrogenation combined with condensation also takes place. Benzene, methylcyclohexane, *m*- and *p*-xylene, ethylbenzene, ditolyl and dimethylanthracene have been isolated from the products of the action of aluminum chloride on toluene at the boiling point.[47] From xylenes and the same catalyst benzene, toluene, pseudocumene, mesitylene and durene were recovered.[48] Isomerization of *o*- and *p*-xylenes to *m*-xylene at 100°C. was noticed by Heise and Töhl.[49] Later, Popov[50] obtained 7 per cent of benzene and 11 per cent of toluene by heating xylene at its boiling point under ordinary pressure with 2 per cent of aluminum chloride. He also noticed that the more resistant *meta*-isomer accumulated upon recycling unreacted xylene. Dealkylation of aromatic hydrocarbons by aluminum chloride has been studied by Orlov and Solodar',[51] who noted that the yield of low-boiling products increased with rising temperature and with the concentration of aluminum chloride, the optimum amount of the latter being 4 per cent. Demethylation of xylene under the influence of the halide and hydrogen chloride resulted in poor yields though a continuous process was developed whereby the production of toluene could be raised to about 25 per cent.

In a similar way, the chloride causes rearrangement of side chains in many other alkylbenzenes. Ethylbenzene is converted by it to benzene, diethylbenzene and triethylbenzene.[52] Isopropylbenzene is decomposed to furnish benzene and diisopropylbenzene, and *n*-butylbenzene is partly transformed into benzene and dibutylbenzene.[53] On the other hand, Ipatieff and Pines[54] report that alkylbenzenes react in certain solvents, such as cyclohexane and decahydronaphthalene, to yield the alkyl group as a paraffin, when in the presence of aluminum chloride. Thus, propylbenzene in cyclohexane yields propane. Decahydronaphthalene served to facilitate this reaction to a greater degree than did the cyclohexane, as the results in Table 47 indicate.

TABLE 47.—*Paraffins from Alkylbenzenes.*

Aromatic Hydrocarbon Used	Paraffin Formed	In Cyclohexane, % Yield	In Decahydronaphthalene, % Yield
Toluene	None	0	0
Ethylbenzene	None	0	0
Isopropylbenzene	Propane	33	53
sec-Butylbenzene	Butane	35	71
ter-Butylbenzene	Isobutane	61	94
2-Methyl-3-phenylbutane	Isopentane	60	..

It was pointed out that this reaction might be of considerable use in determining the structure of alkyl groups attached to an aromatic nucleus.

In the case of the polynuclear aromatic hydrocarbons under similar conditions, the main reaction observed is one of dehydrogenating condensation. In this way, naphthalene is partly changed into 2,2′-dinaphthyl, and phenanthrene undergoes internal rearrangement with loss of hydrogen to give 2,3,10,11-dibenzoperylene.[55] The conversion of 1,1′-dinaphthyl into perylene by heating with aluminum chloride at 140°C. was observed by Scholl, Seer and Weitzenböck.[56] 2,2'-Dinaphthyl is said to yield the same hydrocarbon by similar treatment at 130° to 160°C.[57]

INDUSTRIAL APPLICATIONS OF THE POLYMERIZATION OF OLEFINS BY METAL HALIDES

Polymerization of Gaseous Olefins. In countries where petroleum deposits are small, or lacking, the possibilities in polymerization of the olefins to synthetic lubricating oils have aroused considerable interest. When unsaturated hydrocarbon mixtures such as those derived from the cracking of petroleum distillates are treated with Friedel-Crafts agents, not only do polymerizations take place, but also condensation reactions combining olefins with any aromatic or naphthenic hydrocarbons present. Such reactions are more fully discussed in Chapter 24, but some consideration of them will be given in the present connection.

Petrov, Antzuz and Pozhiltzeva[58] investigated the reactions of a gas containing 20 to 33 per cent of olefins with aluminum chloride in a petroleum ether suspension, under 40 to 60 atmospheres pressure. The experiments were run first at room temperature, when a free oil and a combined sludge were formed. The former appeared to consist largely of paraffins and naphthenic hydrocarbons with long side-chains. The combined oil was freed from the aluminum chloride-hydrocarbon complex by the action of water. Distillation curves of both these oils indicated a smaller number of chemical individuals than similar fractions from natural petroleum.[59] The viscosity-temperature curves of the new materials compared favorably with the curves of American petroleum oils of similar viscosity.

At 100°C. the reaction was more rapid,[60] and the resultant substances quite different in character from those obtained by room-temperature reaction. The free oil now contained appreciable proportions of unsaturated hydrocarbons, and the quantity of combined oil was notably smaller. Moreover, the higher-temperature reaction produced lubricants characterized by steeper viscosity-temperature curves. Though benzene had not been present initially, considerable quantities of hexaethylbenzene were isolated from the reaction products.

Working with a mixture of lower paraffins and olefins (ethane, ethylene, propane, propene, butane and butene, with 72 per cent total olefins) Potolovski and Atalijan[61] obtained a product consisting of about 50 per cent gasoline and kerosene and 50 per cent oils. In this case the reaction was conducted for 10 days at room temperature. However, they found that raising the temperature of polymerization to 70°C. favored formation of lower boiling products.

Schildwächter[62] conducted some experiments condensing ethylene with various substances, such as naphthalene, tetralin and coal-tar oils, in the presence of a

[59] D. L. Woodhouse (*J. Inst. Pet. Tech.*, 1934, **20**, 1057; *Chem. Abs.*, 1935, **29**, 1236; *J. Inst. Pet. Tech.*, 1935, **21**, 18A) became interested in these ethylene-polymer oils during the course of some studies on the carcinogenicity of mineral oils. It had been shown that products subjected to high temperatures in the course of their preparation were more apt to have biological effects than similar material prepared by low-temperature processes. These considerations led him to test the polymer oils composed of few chemical components, arising from known sources under known conditions and at no time subjected to high temperature. Experimentation showed that these materials displayed distinctly less carcinogenic power than did certain natural petroleum oils.

[60] According to L. A. Gukhman and E. Andreeva (*Azer. Neft. Khoz.*, 1934 (7-8), 117; *Chem. Abs.*, 1935, **29**, 6036) the polymerization of cracked distillates by aluminum chloride is 7 to 10 times as rapid at 115° to 130°C. as at 50° to 60°C.

halide catalyst (such as aluminum chloride) under pressure. With naphthalene, at a temperature of 100° to 180°C. and 5 per cent of the catalyst, the yield contained about 85 per cent of bright lubricant which did not darken upon standing. Molecular weight determinations indicated four or more ethyl groups in the resulting naphthalenic molecules. The viscosity-temperature curves of one fraction of this ethylated naphthalene were comparable to those of Pennsylvania crude motor oils of similar viscosity. The ethylation of tetralin yielded only about 27 per cent of substances having the desired qualities, the remainder having lower viscosities and corresponding to di- and tri-ethylated tetralin. Coal tar was ethylated at temperatures between 290° and 330°C., the product (33 per cent) in this case being a good grade of lubricant, stable and free of asphalt. All the oils showed a good measure of resistance to oxidation. By means of the silent electric discharge, the viscosities could be further increased.[63]

Atkinson and Storch[64] polymerized ethylene in two steps by two methods. Thermal polymerization at 370°C. under a pressure of 70 atmospheres was followed by treatment with aluminum chloride at normal pressure. The resultants were a free oil yielding lubricant fractions under vacuum distillation, and a combined oil. This latter was liberated from the complex by decomposition with ice water and proved to be highly unsaturated and dark in color. The lubricant fraction of the free oil (about 30 per cent of the raw material) gave viscosity indices comparable with those of oils obtained by direct treatment of ethylene with a Friedel-Crafts agent.[65] From an investigation of the polymers formed in the reaction of different pentene isomers in the presence of halide catalysts, Waterman, Leendertse and Makkink[66] concluded that the degree of ramification of the starting material has little influence on the viscosity of the resultant oils. Experiments were reported in which pentene-2, trimethylethylene and *asym*-methylethylethylene polymers were studied, particularly as regards their viscosities. The polymers prepared under similar conditions exhibited very closely analogous viscosity indices and viscosity-temperature curves.

Lubricating oils have also been manufactured by treating a highly polymerized isobutene product in a hydrocarbon oil with a condensing agent such as aluminum chloride at 40 to 80°C.[67] Polymerization of isobutene may be made a selective process, Mueller-Cunradi and Otto[68] report. Thus it is possible to remove isobutene from mixtures containing other olefins, (including butenes). Boron trifluoride is the catalyst suggested in this process, though aluminum chloride, or titanium tetrachloride may also be used. The investigators state that at room temperatures, short contact times (of the order of one minute) permit polymerization of isobutene, and facilitate separation of this olefin from the mixture. Temperatures up to 100°C. may be employed, although at these higher temperatures the polymerized products tend to decompose to di- and trimeric compounds. It is said that a mixture of 1 part of isobutene and 2.5 parts of normal butene may be separated by treatment in this way with boron trifluoride at room temperature, so that less than 0.5 per cent of the isoolefin remains unaltered. The isobutene may be recovered from the oily polymer by distilling the latter over activated carbon at 300°C.

---

[63] In this connection, A. D. Petrov (*Chim. Tverd. Topl.*, 1934, **5**, 632; *Brit. Chem. Abs.* **B**, 1936, 52) has shown that the action of the silent electric discharge differs from that of aluminum chloride in that the former polymerizes paraffins, naphthenes and aromatics as well as olefins. See also Chapter 9.

Polymerization of Liquid Olefins. The higher olefins boiling in the gasoline or kerosene range would appear to furnish, on polymerization, fractions whose properties are somewhat superior to those obtained from similarly treated gaseous olefins. Petrov and Pozhiltzeva[69] secured oils from the cracked kerosene fraction of sapropelite tar oils in very low yields at atmospheric conditions, but under seven atmospheres pressure and at a temperature of 200°C. a 25 per cent yield of a fraction boiling above 240°C. was obtained. The complicated nature of the original cracked distillate leads to complex polymerization and condensations; detailed examination of the fractions led to the conclusion that the olefins are polymerized to naphthenes, and also are converted, with aromatics present, to alkylaromatic hydrocarbons. A condensation of naphthenes with olefins also takes place, forming in all probability, dicyclic naphthenic hydrocarbons. They report that the oils obtained by condensing olefins with naphthalene are very similar, particularly in their temperature-viscosity characteristics, to Davis and Blackwood's Paraflow.[70]

FIG. 64.—Plant for Synthesis of Lubricating Oils by Olefin Polymerization with Aluminum Chloride. (F. W. Sullivan, Jr., V. Voorhees, A. W. Neeley and R. V. Shankland)

Zherdeva[71] investigated the possibilities of making aviation lubricants from the kerosene distillates produced in the cracking of paraffin wax and slop oils. Condensation was effected by treatment with 3 per cent of anhydrous aluminum chloride at 60° to 70°C., forming two layers. From the upper layer, basic oils were obtained by concentrating after neutralization and water washing. The lower layer (about 10 per cent of the total) consisted of a complex formed between the catalyst and various hydrocarbons. Decomposed with water, this yielded a dark oil. It was considered that the presence of aromatic hydrocarbons in the original material affected the quality of the product adversely. Good lubricants were obtained from a kerosene fraction secured by cracking paraffin bottoms, however.

Technical Processes for Synthesis of Lubricants. For this type of synthesis, Sullivan and Voorhees[72] suggested employment of a distillate having a final boiling point under 260°C. produced by vapor-phase cracking of high-wax content oils (such as slack wax or sweater oil). By polymerizing such fractions with one-half to 4 per cent of anhydrous aluminum chloride at 80°C. for 15 to 20 hours, or between 38° and 80°C. for not more than 50 hours, lubricating oils of low viscosity-temperature coefficients, low specific gravity and low carbon-forming tendency are obtained. Chittick[73] reports that treating a cracked gasoline with a small amount of aluminum chloride (about 0.5 per cent) serves to convert the gum-forming constituents present into lubricant-like bodies. Polymerization is carried out at a temperature of about 260°C. under conditions which permit the hydrocarbons of the gasoline range to distill off. The residual oil formed is washed with water and caustic alkali. After treatment with fuller's earth, it may be used as a lubricating oil blending stock.

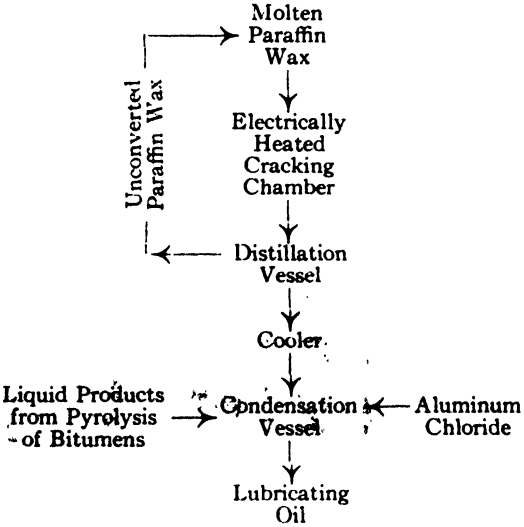

FIG. 65.—Flow Diagram for Condensation of Aromatic Hydrocarbon Material with Higher Olefins from Paraffin Wax. (H. Zorn, M. Müller-Cunradi and W. Rosinsky)

Oils have been produced by condensing the unsaturated liquid products of vapor-phase cracking of paraffin wax with various cyclic hydrocarbons such as naphthalene, anthracene or cyclohexane. Reaction takes place at temperatures up to 150°C. in the presence of one of the Friedel-Crafts agents.[74]

It has been suggested that liquid hydrocarbons from the pyrolysis of bituminous materials be condensed with higher liquid aliphatic olefins (such as may be formed by cracking paraffin wax). Condensation is effected in two stages, part of the product being treated in the first stage. This treated portion is then mixed with the remainder of the material prior to the final condensation.[75] Halloran and Chappell[76] recommend the use of unsaturated hydrocarbons extracted by the treatment of petroleum with sulphur dioxide. Egloff[77] has flash distilled the residues produced in cracking heavy oils, and contacted the vapors with aluminum chloride. Osterstrom's process[78] reacts a mixture of the residual oil derived from cracking paraffin wax and a fraction of unsaturated hydrocarbons (boiling at 215° to 370°C.) from the vapor-phase cracking of gas oil.

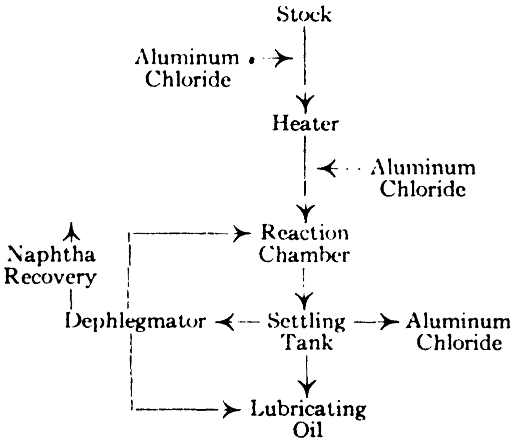

FIG. 66.—Flow Scheme for Lubricating Oil Synthesis from Sulphur Dioxide Extracts. (R. A. Halloran and M. L. Chappell)

The list of suggested raw materials is quite diverse. Such substances as cracking or hydrogenation products of mineral oil and coal, paraffin wax and petroleum jelly, alcohols, organic acids or esters of high molecular weight can all be converted to a species of lubricating oils by polymerization or condensation in the presence of the metal halides; this condensation being preceded in some cases by halogenation.[79] The products obtained may be given greater resistance to oxidation by the addition of 0.05 to 10 per cent of certain organic substances (such as aromatic ethers or cyclic compounds containing sulphur) or elementary sulphur to the raw materials.[80]

The fraction of a liquid-phase product boiling between 150° and 450°C. (after purification by a solvent process) can be cracked a second time in the vapor phase, sometimes with the aid of catalysts, to yield a mixture of unsaturated hydrocarbons which can be polymerized by aluminum chloride to produce lubricants.[81]

Fischer, Koch and Wiedeking[82] have prepared lubricants from dichlorinated paraffinic oils (such as the so-called "Kogasin" synthesized[83] by catalytic combination of carbon monoxide and hydrogen) utilizing activated aluminum chloride. The oils so prepared are said to compare favorably with natural products as regards resistance to oxidation, coking residue and pour-point.

It is frequently advantageous to purify the materials to be polymerized before they have undergone this treatment. Many crude olefin mixtures will, under catalysis, release corrosive substances damaging to the equipment; in others there are impurities which are more readily removed before the molecular weights have been increased.

One type of purification process recommends treatment of the cracked distillates with 60° Bé. sulphuric acid, followed by 20° Bé. alkali prior to polymerization.[84] However, purification may be attained by a preliminary treatment with not more than 2 per cent of the catalyst to be used, at a temperature not lower than that planned for the polymerization proper. Thus, the 65° to 75°C. fraction of a vapor-phase cracked gasoline may be treated at 70°C. with one gram of aluminum chloride per 100 cc. of liquid, the mixture distilled and the distillate then polymerized with 4 grams of the chloride per 100 cc. at 30°C. for 22 hours.[85]

A modification, involving the use of an ethylene-aluminum chloride complex as catalyst instead of the halide itself, has been suggested by Haeuber for the conversion of cracked distillates at temperatures of 100 to 180°C.[86] Martin, Grimme and Koppelmann,[87] on the other hand, suggest preparing a catalyst for cracking processes by the interaction of aluminum metal and hydrogen chloride. The metal is suspended in a substance capable of undergoing the Friedel-Crafts reaction, such as benzene, in the presence of a small amount of aluminum chloride. Hydrogen chloride gas is bubbled in, forming a complex said to be suitable for use as a cracking catalyst. Since the halide catalysts are destroyed by water, it is important that they be protected from moist gases. Kuentzel and Geissman[88] suggest that this be accomplished by passing the raw olefins over used catalyst before contacting the material with the active polymerizing agent. Caudri[89] reported making a lubricating oil from a cracked gasoline, using a two-stage polymerization process. The distillate, which may contain substances tending to poison the Friedel-Crafts agent, is first contacted with a small amount of the catalyst (e.g., aluminum chloride) at 60° to 130°C. for a time sufficient to polymerize the poisoning substances. The remainder of the material is separated off, and treated with a further quantity of aluminum chloride to bring about polymerization to produce a lubricating oil.

By heating the unsaturated hydrocarbons with a metal halide at a temperature lower than 200°C. with an oil-miscible promoter (such as carbon tetrachloride, methyl chloride or amyl chloride) which is capable of yielding hydrogen chloride in the presence of the metal halide, the yield of viscous products may be increased, according to Snow.[90]

Ayres and Smith[91] have made lubricants, as well as other products (e.g., kerosene and various refined hydrocarbons), by treating petroleum stocks with aluminum chloride (at temperatures not exceeding 150°C.) in the presence of an excess of chlorine or hydrogen chloride.

OTHER POLYMERIZATION PRODUCTS OF OLEFINS

Olefin polymerization can be carried further to give very viscous oils, tarry products and synthetic resins.[92] Some of these may be added to lubricating oils for various reasons, and others, particularly the resins, find use in coating compositions.

The complex hydrocarbon mixture obtained by heating pyrene with aluminum chloride,[93] is said to be capable of imparting a greenish-yellow fluorescence, or bloom, to lubricating oils when added to the extent of about one-thousandth of one per cent. Smith[94] suggests a similar use for materials obtained from chloride sludge formed in the refining of hydrocarbon oils of naphthenic character. Smith's method employs centrifuging, filtering or washing with dilute sulphuric acid and subsequent neutralization to recover the bloom agent in a concentrated form. Rosson and Fasce[95] find that a solid coloring matter, or dye suitable for coloring lubricating oils may be produced by an aluminum chloride condensation. The anhydrous catalyst is allowed to react with a mixture containing an aromatic such as benzene or toluene and also a polycyclic aromatic such as naphthalene or anthracene, at a temperature of 45° to 55°C. The catalyst is separated from the reaction mixture, and the coloring material recovered from the products.

Condensed materials of high molecular weight capable of lowering the pour-point of lubricants may be prepared by the action of the halide catalysts on higher petroleum hydrocarbons. If waxy hydrocarbons, with or without aromatics, are condensed with aluminum chloride and the lighter inactive materials boiling below about 370°C. are separated out, an active pour-point depressant with a mean molecular weight above 1200 may be recovered by a wax-precipitating agent.[96] Similar reactions on paraffin wax,[97] petrolatum[98] and hard or soft paraffin[99] produce stocks valuable in improving the properties of lubricants.

Pevere[100] states that a tarry residue derived from the aluminum chloride treatment of an aromatic hydrocarbon may have application in dewaxing lubricating oil. The condensation product resulting from this treatment is distilled under high vacuum to obtain a residue consisting essentially of a tarry material which is not volatile at 310°C. under 10 mm. of mercury pressure. It is reported that this material may be added in proportion of less than 5 per cent to the oil to be treated, to bring about precipitation of the wax on cooling.

Double compounds of aluminum chloride and an olefin have been proposed as agents for the removal of gum-forming compounds from gasoline.[101] Sumpter has removed these compounds with the aid of aluminum chloride and an alkali metal or alkali-earth metal chloride, such as potassium, sodium or barium chloride, in equivalent molecular proportions.

Varshavskii and Shenfinkel[102] state that a drying oil may be obtained by treating with cold water the aluminum chloride complex resulting from the polymerization of a gasoline distillate (polymerized at 100° to 120°C. for four hours). Waterman[103] has prepared an analogous drying oil from a cracked mineral oil containing polyolefins. The oil is treated with a metal halide (e.g., $AlCl_3$) at below 65°C., and the polymerized products are separated from the sludge formed in the reaction. This material is neutralized, and subjected to a non-cracking distillation, to secure a residue in which the drying components are concentrated.

Waterman, Leenderste and Ligtenberg[104] treated a cracked distillate with aluminum chloride at room temperature for four to five hours. Under these conditions polymerization proceeds to a resin soluble in organic solvents and capable of emulsification in ammoniacal water to a stable, spongy composition.

Thomas[105] has worked with a type of resin produced by the co-polymerization of an olefin and a diolefin. Using hexadiene and olefins such as trimethylethylene or ethylene, the substances are reacted in the presence of aluminum chloride. The finely divided catalyst is fed in slowly, and cooling is provided to maintain the temperature between 25° and 35°C., as below 20°C. the reaction is slow and the product soft. Temperatures above 20°C. produce harder resins, but above 65°C. the color is poorer. The amount of catalyst required varies with the size of the batch; with 25 gallon operations, 1.4 per cent of catalyst is used, while with 100 cc. runs, 3.5 per cent of catalyst is needed. Treatment lasting 4 to 6 hours gives optimum results. The product from this treatment is neutralized in alcoholic ammonia, yielding a granular precipitate. The addition of a hydrocarbon solvent (such as benzene) and filtration free the resinous material of decomposition products from the metal chloride. The resin can be recovered from the hydrocarbon solvent.[106] This same investigator has reported[107] that resins of this type are reactive, showing high iodine numbers. In consequence, they can be further reacted with glycerol and castor oil to produce a resin soluble in varnish solvents which dries to produce a film said to be clear and elastic and resistant to acids and alkalies.

[106] C. A. Thomas and W. H. Carmody U. S. P. 2,060,404, Nov. 10, 1936, to Monsanto Petroleum Chemicals, Inc.; *Chem. Abs.*, 1937, **31**, 480) state that synthetic resins of the type prepared by polymerization of diolefins in the presence of a Friedel-Crafts agent may be decolorized by a solvent process. The resin is pulverized and taken up in a non-aromatic hydrocarbon solvent such as pentane, hexane or naphtha, and agitated for about 15 minutes with an active bleaching clay. The solution is then separated from the clay and coloring matter, and the solvent removed (e.g., by distillation). The decolorization is said to be more satisfactory when low boiling solvents such as pentane or hexane are employed, than when the higher fractions such as octane or naphtha are used. The final decolorized product has varnish making properties substantially similar to those of the original untreated resin, the investigators state.

Berger[108] has suggested that a resin may be produced from the halide sludge obtained in aluminum chloride refining processes applied to hydrocarbon oils. The sludge produced by treating a cylinder oil stock with the catalyst for 2 hours at 120°C. was used as raw material in one instance. This was freed of entrained oil by extraction with solvent naphtha, and then treated with free chlorine at 95°C. for four hours. At the end of this time the mass was washed in hydrochloric acid, and subsequently decomposed into a water solution and a solid, dark-brown, thermoplastic substance insoluble in any ordinary solvent. It is reported that carbon tetrachloride, chlorinated naphtha, chlorinated propane or pentachlorobutane may be used in place of free chlorine in this process.[109]

Chapter 7

Production of Hydrogen and Carbon by Pyrolysis of Hydrocarbons

The thermal decomposition of all hydrocarbons produces, ultimately, carbon and hydrogen. In the temperature range 600-1400°C., however, methane is also secured, and the proportions of the two gaseous constituents (methane and hydrogen) at sufficiently long contact times are defined by the equation,

$$CH_4 \rightleftharpoons C + 2H_2$$

Equilibrium in this system corresponds with almost complete decomposition of methane at slightly above 1000°C., but in actual practice higher temperatures are necessary. In considering the yields of carbon and hydrogen from hydrocarbons, this reaction is, therefore, of prime importance.

In addition to the temperature factor, the pyrolysis of methane is influenced by the time of contact, pressure, the presence of catalytically active substances and the use of diluents or hydrogen. In particular, the time factor exerts a very great influence both on the character of the products and the extent of dissociation. In the temperature range of 1000-1200°C., methane decomposes mainly into acetylene, ethylene and aromatic oils at contact times of the order of 0.1 second. On the other hand, at heating periods of 40 to 45 seconds at 1100°C. (or 5 seconds at 1250°C.) complete decomposition of methane into its elements can be achieved. The carbon obtained is gray, has a high apparent density and is unsuitable as a pigment or as a substitute for lampblack. According to Padovani,[1] this material is crystalline and graphitic. Metallic surfaces favor graphitization and the carbon tends to form a thick crust on the walls of the reaction tube. It has been shown by the same investigator that a more useful form may be produced, together with aromatic oils, by conducting the pyrolysis of methane at contact times intermediate between those necessary for the complete decomposition on the one hand and, on the other, for the optimum production of aromatic liquids. By cracking methane under these conditions at 1100°C., in such a way that most of the carbon formed was carried off in the gas, he obtained from one cubic meter about 200 g. of carbon black, 35 g. of aromatic oils and 1.4 cubic meters of gas consisting of two-thirds hydrogen and one-third residual methane.

Catalysts which accelerate the decomposition of methane include metals such as iron or nickel, and graphitic carbon.[2] Certain special contact agents have been advocated, but their value is rather doubtful, since frequent elimination of deposited carbon (from them), by oxidation with air or by steam, is usually necessary. A catalyst consisting of 5 parts ferric oxide, 2 parts calcium carbonate, 1 part nickel oxide and 0.5 part manganese dioxide supported on iron filings has been used by Candea and Kühn[3] for cracking methane at 800-1000°C. In this instance, the carbon was removed by steam. However, the dissociation of methane appeared to take place chiefly at the exposed surface of the reaction chamber and there was reason to believe that catalytic action was of secondary importance compared with the effect of increasing the heating area. Hence, industrial operation is usually carried out in the presence of refractory materials of large surface and high heat content.

---

With regard to the other factors influencing the separation of methane into its elements, dilution with an inert gas such as nitrogen slows down reaction by reducing the partial pressure of the hydrocarbon. It also decreases the velocity of the reverse reaction (combination of carbon and hydrogen) by exerting the same effect on hydrogen, these two opposing influences tending to compensate each other to some extent. Dilution with hydrogen reduces the speed of dissociation and increases the rate of combination so that, in effect, it retards the transformation of methane into its elements in two ways; moreover, this effect becomes more and more pronounced as complete reaction, $CH_4 \rightarrow C + 2H_2$, is approached.

The successful production of carbon black by thermal decomposition appears to depend on the use of a brief contact time, combined with some method of preventing deposition of the carbon on the highly heated walls of the chamber. Any attempt to produce carbon in a heated tube invariably results in the settling of a layer of hard, gray, lustrous material on the walls, which, owing to its poor heat conductivity, soon insulates the reaction zone from the source of heat. In the Thermatomic[4] process decomposition of hydrocarbons takes place in a refractory checkerwork and the carbon black is swept out of the cracking furnace in the gas stream. Any carbon deposited on the checkerwork is burnt out in the subsequent cycle, in which the refractory material is heated to about 1300°C. by gas firing. In some instances a blanket of hot gas, separating the hydrocarbon from highly heated walls, and thereby simulating a wall-free reaction space, is employed to prevent the formation of hard carbon on the sides of the reaction tube. In the "Gastex" process,[5] parallel streams of hydrocarbon gas and air are passed through the reactor in such a way that combustion occurs at the air-gas interface which supplies the heat to decompose the hydrocarbon. The latter does not come in contact with the walls of the system, the energy for decomposition being supplied by flames.

A somewhat similar method has been used by Pidgeon[6] for producing carbon black from the lower paraffin hydrocarbons in what is virtually a wall-free reaction space. He carried out decomposition in porous tubes, through which a certain amount of inert gas was diffused. This was accomplished by placing the refractory tube in a gas-fired furnace, in which the pressure (of the inert gas) was greater than that in the tube, thus maintaining a blanket of flue gas to separate decomposing hydrocarbon from the walls of the reaction tube.[7] Under these conditions, about 19 lbs. of carbon black were obtained from 1000 cubic feet of methane at a temperature of 1350-1400°C. and an apparent contact time of 0.25 second. By dissociation of a mixture of 70 per cent propane and 30 per cent butane at about 1350°C. and an apparent contact time of 0.1 to 0.2 second, yields of carbon black amounting to 60 lbs. per 1000 cu. ft. (60 per cent of theoretical) were secured.

The particle size of the carbon depended largely on the time of contact, more prolonged heating resulting in larger particles. The carbon blacks made by this method were similar to soft blacks in that they had a high density, low sorptive power, accelerated the cure of rubber stock and gave similar resistance to aging and abrasion. However, in their ability to impart stiffness to rubber stock, they occupied a position intermediate between the channel and soft blacks.

For the commercial production of both carbon and hydrogen by thermal decomposition, natural gas, especially the so-called "dry" gases, constitutes an appropriate raw material because of its abundance and low price. An ideal process of this type would be one capable of yielding simultaneously relatively pure hydrogen gas and high-grade carbon, the latter useful as a substitute for carbon black or lampblack. Unfortunately, the available data seem to indicate that under conditions which give a gas rich in hydrogen, the carbon obtained is of poor quality and valueless, except as a fuel. On the other hand, procedures which favor the formation of more valuable types of carbon, do not yield at the same time a very pure hydrogen. In the Thermatomic process,[8] 1000 cubic feet of natural gas furnishes 1800 cubic feet of a gas containing 81 per cent of hydrogen, 6 per cent methane, and a residue of nitrogen, oxygen and oxides of carbon. Also, it has been reported that small quantities of acenaphthylene and pyrene are secured from this process.[9] For the preparation of hydrogen from natural gas, the catalytic reactions with steam,[10]

$$CH_4 + H_2O \longrightarrow CO + 3H_2$$

and

$$CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2$$

or incomplete combustion,

$$CH_4 + \tfrac{1}{2}O_2 \longrightarrow CO + 2H_2$$

would appear to be more applicable.

In the technical production of hydrogen from hydrocarbons by pyrolysis, the carbon simultaneously formed is utilized as a fuel. For example, the endothermic decomposition may be carried out in the presence of highly-heated refractory material, on which the carbon is deposited. As soon as the temperature of the contact mass has fallen to a lower limit, the carbon is burnt off by means of an air blow, raising the temperature of the refractory mass in readiness for another dissociation cycle. In processes for the manufacture of higher grade forms of carbon, the hydrogen-containing gas simultaneously formed is usually employed as a fuel.

PRODUCTION OF CARBON AND HYDROGEN BY SIMPLE THERMAL DECOMPOSITION

Spear and Moore[11] obtained carbon black by separately preheating natural gas and a diluent gas, e.g., hydrogen, mixing the two, and effecting decomposition in a heated zone of refractory checkerwork. The products were rapidly cooled by water sprays and passed to a separator. Dilution of a hydrocarbon gas with at least twice its volume of hydrogen, followed by passage of the mixture over highly heated surfaces (see Fig. 67) is recommended by the same investigators.[12] The black secured is reported as a new product,[13] having an apparent density of about

0.37 and a maximum loading value[14] in rubber (when compounded as a reinforcing agent) in excess of 100 but not substantially higher than 150. The use of a checker-filled converter is also reported by Frenkel.[15] In this case the product is collected, mixed with water and subjected to high pressure. It is then sprayed with a stream of hot combustion gases to effect flash evaporation of the water. Brownlee[16] suggests that after decomposition of natural gas by contact with hot checkerwork for a short period, the gaseous yield be quickly cooled by refrigerated residual gas from a previous operation. The resulting black has a greater tinting power,[17] lower apparent density and a flocculence not greater than that of channel black. Reed[18] makes use of a vertical chamber packed with checkerwork constructed of units having wedge-shaped edges which project in a direction counter to that of the gas flow (see Fig. 68). The checkerwork thus presents only inclined or vertical surfaces to the flow, has no pockets in which the carbon can collect and no horizontal surfaces capable of causing abrupt contact and separation of carbon. The system is heated periodically by direct combustion. Wilcox[19] effects the conversion

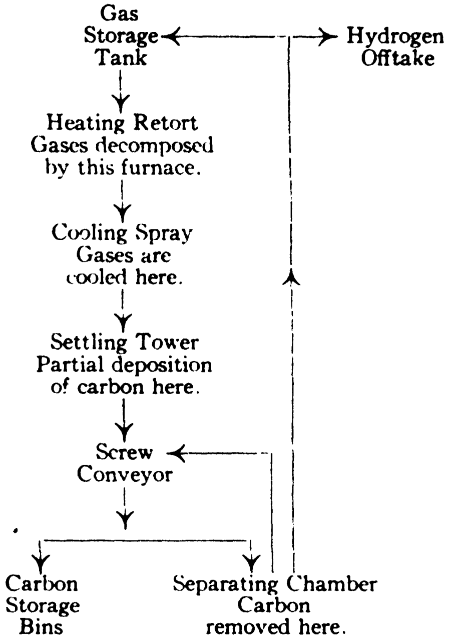

FIG. 67.—Flow Diagram for Carbon and Hydrogen Production by Thermal Decomposition of Hydrocarbons. (E. B. Spear and R. L. Moore)

of natural gas or other hydrocarbon gases into carbon black and aromatic compounds by passage through an elongated conduit with a contact time of 1 to 3 seconds. The refractory tube is internally heated to 980-1200°C. by combustion gases. The hydrocarbon is decomposed while flowing in a direction countercurrent to the heating gases and the carbon black is recovered from the partially cooled gaseous product by electrostatic precipitation, and subjected to further cooling and oil-scrubbing to remove liquid hydrocarbons. In an effort to secure the maximum amount of carbon black, Willien[20] conducted natural gas without steam through a

bed of incandescent coke. The reformed gas passed through a Cottrell precipitator and a Cyclone dust collector which recovered 98 per cent of the carbon black. Richardson,[21] to control the relative amounts of carbon black and gaseous products, suggests that a mixture of steam and hydrocarbon gas in the proportion 3:1 by volume be heated sufficiently to effect thermal decomposition.

[20] L. J. Willien, *Am. Gas. Assoc. Proc.*, 1935, 17, 779; *Chem. Abs.*, 1936, 30, 3967; *Brit. Chem. Abs.* B, 1936, 726.

A process for the manufacture of a gas rich in hydrogen (and free from carbon black) from natural gas or oil-still gas is described by Terzian,[21a] who brings about the decomposition in the presence of a heated bed of fuel (coke), which is intermittently air-blasted. All liberated carbon is retained for subsequent utilization during the air-blow, and the porosity of the fuel bed is preserved by reducing the temperature of its surface prior to the passage of the hydrocarbon gas. Towne[22] suggests activated alumina or bauxite, pumice or fuller's earth instead of coke for this type of treatment.

To obtain large percentages of hydrogen by pyrolysis of hydrocarbons it is advocated that the gaseous raw material be conducted through a cylindrical mass of hot crushed refractory material arranged so that the central portion of the mass is more porous than succeeding outward portions, the object being to allow longer periods of contact in the cooler areas so that there may be more uniform cracking efficiency throughout the refractory material.[22a]

As a raw material from which hydrogen may be obtained, Turner and Keene[23] propose Pennsylvania anthracite. When samples were heated slowly to 1036°C. under an initial pressure of less than 1 mm. the volatile matter contained 75-79 per cent hydrogen, applicable for welding purposes and hydrogenation.

Pyrolysis of acetylene, with or without air,[24] and at moderate temperatures (180°C.), has been used to make a special quality of carbon black, usually referred to as acetylene black. Day[25] has found that the black secured from purified acetylene had an ash content of 0.01 to 0.05 per cent, and could be used for oxidation rate studies.

DECOMPOSITION EFFECTED BY PARTIAL COMBUSTION OF HYDROCARBONS

Part of the heat required for decomposition of hydrocarbons may be obtained by partial combustion of the hydrocarbons either with air or oxygen-containing gases. The usual methods of manufacturing carbon black are based on this principle, the carbon being formed by thermal decomposition of unburned hydrocarbons and rapidly removed from the flame zone by impingement on cooled surfaces. Incomplete combustion may also be employed for producing mixtures of hydrogen and oxides of carbon with or without nitrogen.

The preparation of carbon black by incomplete burning of hydrocarbon gases in small-bore refractory tubes is described by Brownlee (see Fig. 69).[26] Another procedure comprises passing hydrocarbon vapors through a sheet of flame, the latter placed near a radiating surface.[27] Beaver[28] effected partial burning of hydrocarbon gases in a series of narrow, flattened burners mounted in the lower part of a heat-insulated chamber. The burners, which are surrounded by air ducts, are mounted in a row with their longer sides parallel so that the flames radiate mainly to each other. The air supply is regulated to about 40-75 per cent of that required for complete combustion and the chamber is so dimensioned as to give a time of contact in the hot zone of about 0.5 to 1 second. The carbon black is recovered from the gases leaving the stack of the furnace. Partial combustion for the manufacture of carbon black is carried out by Keller[29] in a series of narrow ducts, mounted in parallel, vertical planes in an unobstructed, heat-insulated furnace. The hydrocarbon gas is discharged upward and a regulated supply of air is introduced near the lower end of the gas ducts. Bevelling prevents deposition of carbon on the ends of the gas ducts and facilitates streamline flow of both hydrocarbon gas and air at these points.

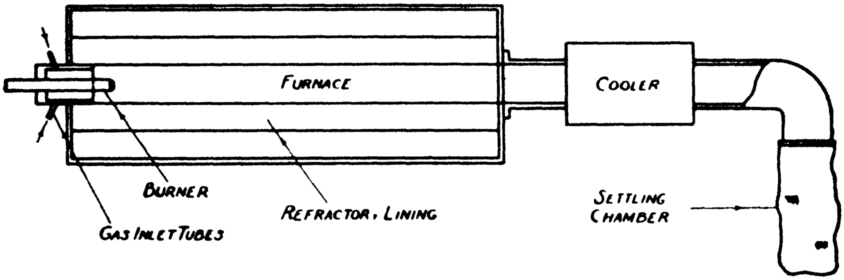

FIG. 69.—Method of Carbon Black Production by Incomplete Burning of Gases in Small-bore Refractory Tubes. (R. H. Brownlee)

The incomplete burning of methane and similar hydrocarbons may be used for the production of mixtures of hydrogen and nitrogen if the carbon monoxide simultaneously formed is removed afterwards from the gas mixture. This latter step may be accomplished, for example, by the conversion of the monoxide to dioxide by reaction with steam (see Fig. 70) followed by elimination of carbon dioxide.[30] The oxidation of methane, expressed by the equation

$$CH_4 + \frac{1}{2}O_2 \longrightarrow CO + 2H_2 + 8 \text{ kg. cal.}$$

is favored by the same catalysts and conditions as the reaction of methane with steam or carbon dioxide. Padovani and Franchetti[31] have investigated this partial oxidation of pure methane and gases of low methane content. In the presence of a nickel catalyst and at space velocities of the order of 500 (i.e., ratio of gas velocity to space), results closely corresponding with the equilibrium values were obtained at 850-950°C. Operation with methane at 900°C. yielded gaseous products containing less than 1 per cent of the hydrocarbon. For the manufacture of carbon black and a mixture of hydrogen and nitrogen in controlled proportions, Wilcox[32] subjects hydrocarbon gases to partial decomposition by passage through conduits heated to progressively higher temperatures. After removing entrained carbon, the gases are diluted with steam and incompletely burned with measured amounts of preheated air. Contact agents such as nickel or iron may be used. The efficiency of a promoter of nickel for the partial combustion of natural gas to carbon monoxide and hydrogen has been investigated.[33] The reaction chamber consisted of a steel cylinder with a lining of refractory fire-clay brick. The lower portion was packed with fire-clay brick and the upper part with nickel catalyst and pieces of fire clay. In the procedure, a mixture of natural gas and steam was conducted into the lower part of the furnace and passed upward. The gases were heated by the hot packing and the contact agent, and were led from the upper portion of the chamber at 1100°C. When the packing had cooled, the conversion process was interrupted and the chamber reheated by combustion of natural gas with excess air. It was stated that in this manner 1.9 cubic meters of steam were admixed with 1 cubic meter of natural gas to yield 3.3 cubic meters of gas containing 64 per cent of hydrogen and 22 per cent of carbon monoxide. Partial combustion of hydrocarbons in the presence of an electric arc has been proposed by Eisenhut[34] for the manufacture of hydrogen-containing gas. Thus, a cubic meter of methane was admixed with like amounts of air and steam. The mixture was then conducted through an electric arc at 1400°C. (see Fig. 71). As the gases left the arc they were led into a mixing chamber containing baffle plates. In this manner a yield of 4 cubic

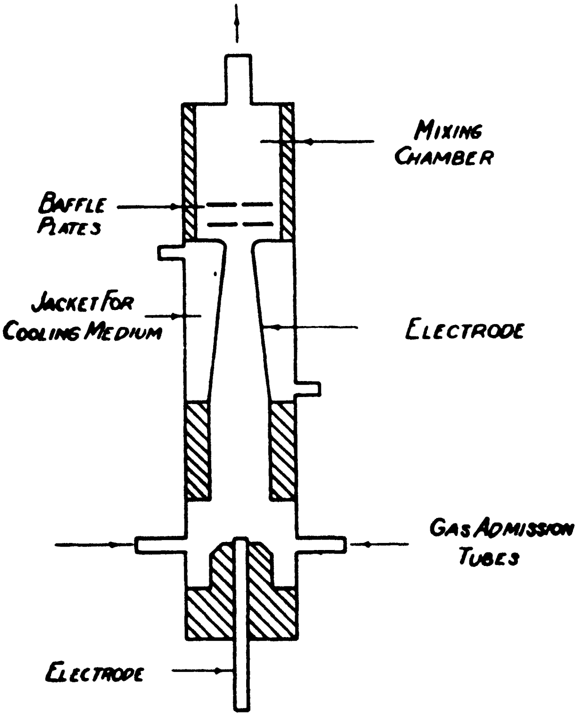

Fig. 71.—Sketch of Apparatus for Partial Combustion of Hydrocarbons in Electric Arc. (O. Eisenhut)

Decomposition by Other Means

A number of methods of preparing carbon blacks by the decomposition of hydrocarbons by electric discharge have been proposed. In the process of Jakosky and Hanson,[35] hydrocarbon oils are conducted through a chamber where they are subjected to the action of a localized high temperature produced by an electric arc. The black is permitted to remain in suspension in the oil and the rate of flow is regulated to maintain its concentration between 8-10 per cent. At higher concentrations, the quality of the black begins to be adversely affected. An apparatus for this procedure, with spaced rotating electrodes (see Fig. 72), has been described by Jakosky and Wieden.[36]

Electrical resistances of high ohmic value are obtained[37] by depositing carbon, furnished by dissociation of a gaseous hydrocarbon (e.g., methane) having a high decomposition temperature (600-800°C.), on an insulating carrier. In this manner formation of an amorphous material is prevented. Excess coating on the carrier is removed by admitting carbon dioxide at a temperature sufficiently low to prevent dissociation of the resulting carbon monoxide.

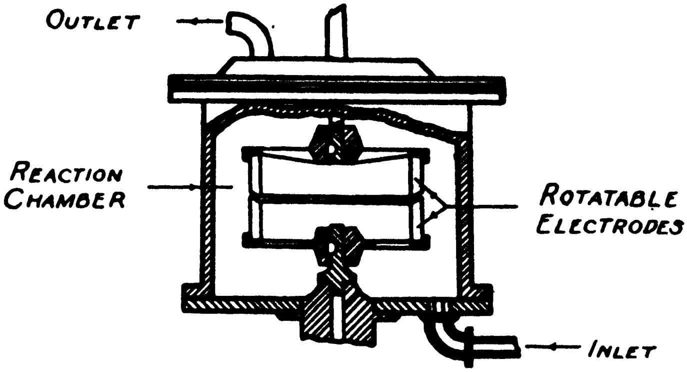

FIG. 72.—Reaction Chamber for Decomposition of Hydrocarbon Oils by Electric Discharge. (J. J. Jakosky and H. J. Wieden, Jr.)

To produce adsorbent carbon, another process is suggested.[38] Coal, lignite, peat or wood may be chlorinated in a suspension of carbon tetrachloride, carbonized by slowly heating to 850°C. and afterwards activated by steam.

DECOMPOSITIONS EFFECTED IN THE PRESENCE OF CATALYSTS

In the pyrolysis of hydrocarbons (such as methane) for the production of hydrogen, it may be expected that the rate of decomposition could be increased by catalysts. In practice, however, the activity of contact agents in reactions of this sort is speedily suppressed by the formation of a protective deposit of carbon, which must be periodically removed by oxidation with air or by passage of steam at high temperatures. Finkel'shtein and Zabolotzkiĭ[39] report the use of fireclay containing 12 per cent nickel oxide, 2 per cent chromium oxide and 3 per cent copper oxide. This catalyst, though not rendered inactive by hydrogen sulphide, will lose its activity if the soot is not eliminated at intervals by steam, forming water gas.

Candea and Kühn[40] found that a good catalyst for the decomposition of methane into its elements at 800-1000°C. was one containing ferric oxide, calcium carbonate, nickel oxide and manganese dioxide in the proportions 10, 4, 2 and 1. Another, consisting of a mixture of 100 parts of aluminum hydroxide, 20 parts of boric acid and 20 parts of silica, is satisfactory for the production of hydrogen from methane at a temperature of about 1200-1250°C.[41] The activity of copper oxide and tin dioxide in the decomposition of natural gas has been studied.[42] When using copper oxide, the rate of flow of the gas was 3 liters per hour. It was said the conversion of the natural gas to carbon and hydrogen began at 400°C. and was complete at 720°C. Employing the same rate of flow of the gas with tin dioxide, it was reported that decomposition took place between 700 and 910°C. but was not complete, even at the latter temperature.

The manufacture of carbon black from carbon monoxide is achieved by Odell[45] by conducting still gases and steam over a bed of solid fuel heated to 880°C. to yield carbon monoxide and hydrogen.

$$C_nH_{2n+2} + nH_2O = nCO + (2n + 1)H_2$$

The oxide is then converted to carbon and carbon dioxide by passing it rapidly through a tower packed with iron or a manganese-iron alloy at 500°C. (see Fig. 73). The gas and black leave the tower and pass to a settling chamber.

PETROLEUM COKE

The oldest method of preparing petroleum coke is by destructive distillation of heavy petroleum fractions in externally heated shell stills. The product from these coking stills is a hard brittle material with an oily luster and corresponding in composition to $C_{100}H_6$. It is one of the purest forms of industrial carbon, containing only a minute amount of ash, though coke prepared from Mexican oils contains some sulphur. The construction and operation of these stills in Russia has been described by Vuiborov,[46] who reports typical yields obtained in the coking of cracked residues. See Table 48.

TABLE 48.—*Yield from Russian Still.*

Coke	10-13%
Gas oil	75.5-82.3%
Gas and loss	7.5-12.2%
Fuel oil	7.0- 8.3%

Composition of Coke (in Per Cent)

Carbon	92.53-94.83
Moisture	1.0-1.4
Volatile matter	3.61-5.22
Ash	0.12-0.3
Iron	0.01
Silicon	0.04
Sulphur	0.39-0.48

The heterogeneous nature of the product resulting from coking petroleum oils has been noted by Simek,[47] who found that a mass of petroleum coke, 40-50 cm. thick, in the bottom of a still is divided into three main strata of which the center layer (the largest) is applicable for carbon electrodes. The lower layer, the crust, is porous, brittle, often graphitized, has a gray to silver gray color and contains some ash. The center and upper layers contain no ash and are black, relatively strong and somewhat elastic. The upper stratum, which is richest in volatile matter, is sufficiently soft to be cut, without crumbling, with a knife and is often returned to the next charge for further coking. It is reported by Simek that petroleum coke made in this way is almost inactive towards carbon dioxide at 1000°C., possibly in consequence of its very low ash content.

Since the advent of commercial cracking operations, the most important type of petroleum coke, from the point of view of quantity produced, is that obtained in cracking stills, where it is deposited in the soaking drum. This coke is very brittle and of honeycomb structure, although its composition depends largely on the type of oil employed and on the cracking conditions.[48] Variations in composition with the oil used are illustrated by Table 49.

Arkansas...........	87.15	4.18	8.67

Petroleum coke is also made by the Knowles process,[49] which employs a wide, flat-bottom oven (see Fig. 74). The floor is heated from below by a series of narrow, parallel combustion chambers and is constructed of silicon carbide. A temperature of 980°C. is maintained during the first operation, which comprises continual pouring of petroleum residues into the oven until a thick layer of coke is formed.[49a] The temperature may then be raised to 1095°C. by further heating. The coke is usually hard and dense[50] and contains very little ash or volatile matter. A high grade material is manufactured in Germany by coking coal-tar pitch in cast-iron retorts. This pitch coke is reported to contain 0.5 per cent ash and the same amount of volatile materials and is preferred for electrode manufacture because of its regu-

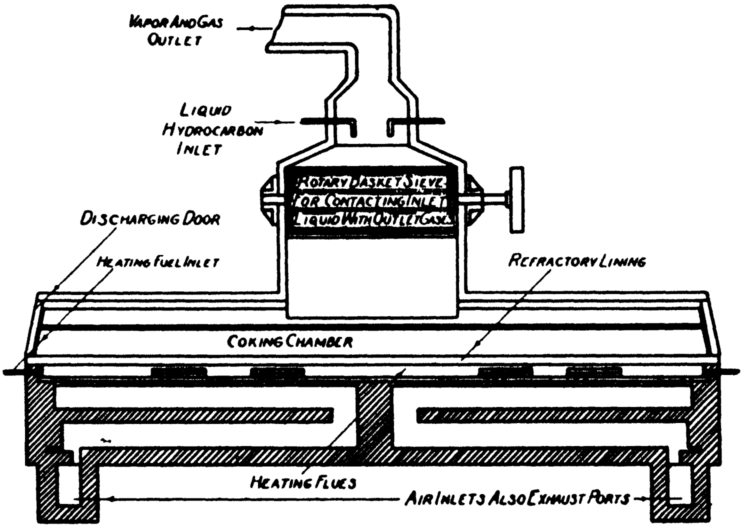

FIG. 74.—Sketch of One Form of Knowles Process Coking Oven. (A. S. Knowles and C. W. Andrews)

larity in quality. When operation is carried out under reduced pressure, yields of 50-60 per cent coke, 30-40 per cent oil and about 5 per cent resinous substances together with some gas and ammonia are obtained.

---

Coking heavy oil stocks by passage of a hot gaseous medium through them is described by Vobach and Rogers.[51] For this purpose, the reaction vessel (see Fig. 75), which is conical with the larger end uppermost, is lined with a frangible material, such as fireclay and water-glass paste. The lining is fractured at the narrow end of the vessel by means of a hydraulic ram, so that the charge can be removed *en bloc*. Petroleum coke containing mineral matter evenly distributed throughout its mass was prepared by Duff[52] by carbonizing a mixture of petroleum and a mineral-bearing substance, such as coal or shale.

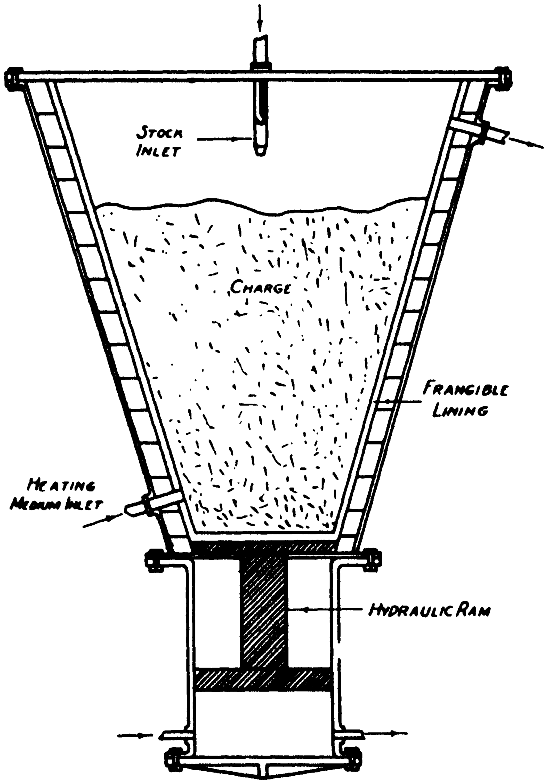

FIG. 75.—Coking Receptacle with Frangible Lining. (A. C. Vobach and H. K. Rogers)

Consumption of petroleum coke for the manufacture of carbon electrodes is increasing steadily, especially in Europe, where 120,000 tons are imported yearly for this purpose. Perhaps the most important use is as a fuel, for which purpose it is said to possess advantages over other solid fuels in that it gives less ash, needs less attention (owing to higher calorific value and consequent reduction in number of fillings) and shows improved sensitivity where thermostatic control is provided.[53] A carbonaceous fuel is prepared by Fisher[54] by mixing pulverized petroleum coke (the volatile matter of which has been previously reduced to 1 to 5 per cent by retorting) with a binder and briquetting the mixture, which may be carbonized afterwards.

---

Petroleum coke has been used as a fuel for industrial boilers and furnaces, but it is not generally employed in metallurgical operations because of its poor mechanical strength and high sulphur content. However, coking still residues are said to compare favorably with coal cokes for foundry purposes except in regard to porosity, and may be used in the manufacture of all grades of iron.[55]

Activated Carbon. Several proposals have been made to produce activated carbon from petroleum coke. Oberle[56] suggests heating as high as 2000°C., under pressures of 50-500 lbs. per sq. in., and in the presence of steam, activating gases or salts, or mineral acids. Volatile reaction products are withdrawn during the treatment. Another method is to mix pulverized coke intimately with heated atomized mercury, or a low-melting alloy, and steam and pass the mixture through a "thermolizing" coil.[56a] The advantages are stated to be a very brief time of contact, good temperature control and prevention of clogging of the system. The activated carbon is recovered from the metal in a subsequent settling operation.

In a process of Faben[57] heavy petroleum residues are destructively distilled by contact with hot combustion gases. The flow of the latter is regulated so that the temperature does not exceed 700°C., and is continued until a coke of low volatile content is produced. This coke is converted into activated carbon by heating to about 900°C. in an oxidizing atmosphere, e.g., superheated steam. Another method consists in digesting petroleum coke with certain reagents (unspecified) in a closed container for 1 hour at 300°F. and for an hour at 800°F.[58] After cooling, washing with water, with an acid solution of 50 per cent strength and then twice with water, it is finally dried with exhaust steam. The yield of coke is 40-60 per cent of the raw material and its ash content is 1 per cent.

Mótusz[59] has reported an interesting sidelight on the use of activated carbon. Four types, Carbonit-Frankfurt, Eponit-Ratibor, Charbon activ-Paris, and Carbo-Merck were employed to clarify wines and the increase in ash content of the liquid noted. He found that the amounts of ash in these carbons (17.64, 11.13, 11.49 and 1.78 per cent, respectively) rendered them unsuitable for such purposes, and recommended an active carbon whose ash content was less than 1 per cent.

The graphitization of petroleum coke is described by Derby.[60] He passes the coke through a vertical furnace where it is progressively heated by surface combustion to 1800°C. (see Fig. 76). A coreless electric induction furnace, which forms part of the apparatus, then raises the temperature to 2500°C.

PURIFICATION OF HYDROGEN

The hydrogen produced by simple thermal decomposition of methane (or its homologues) always contains small amounts of that hydrocarbon and its removal is a matter of technical importance where very pure hydrogen is desired. Because of its inactivity chemical methods of separation are not readily applicable. Of the physical methods, preferential solvent action is usually advocated, although absorption of methane is also possible. According to Karzhavin and Gerchikova,[61] the solubility of methane in low-boiling benzine is sufficient to warrant the use of the latter with hydrogen-nitrogen mixtures, but the washing operation should be carried out at high pressures and low temperatures. Kerosene and heavier oils are not satisfactory for this purpose.

Carbon monoxide, which is usually present in the hydrogen produced by partial combustion of methane with steam, oxygen or air, is an undesirable constituent for many purposes. The extreme solubility of carbon monoxide in ammoniacal cuprous salt solutions has been utilized on an industrial scale for the removal of small amounts from hydrogen-nitrogen mixtures employed in the synthesis of ammonia. It has been found by Zhavoronkov and Reshchikov[62] that ammoniacal solutions of cuprous formate and lactate are superior to those of the chloride and acetate. Cuprous ammonium formate absorbs carbon monoxide more readily than the lactate but the solution is less stable and regeneration more difficult. To prevent the separation of free copper, cupric salts should be present in the solution to the extent of at least 20 grams of divalent copper per liter. Absorption is best carried out at 0-20°C., and regeneration of the solution should take place at 70-80°C. and at atmospheric, or subatmospheric, pressure.

Chapter 8

The Carbon Black Industry. Deposition of Carbon from Flames

Carbon black is essentially pure carbon in an exceedingly fine state of subdivision. It is obtained by incomplete combustion of hydrocarbons in a limited amount of air, and its properties and qualities are greatly influenced by relatively minor alterations in the mode of operation. The so-called gas blacks are the most important, not only in quantity produced but also in quality.

In the case of gas blacks, carbon resulting from the incomplete combustion of the hydrocarbon gas is deposited on cooled surfaces on which the flames are allowed to impinge. The channel, rotating disk, plate and roller methods are all variations of this principle. The channel process is by far the most important of these methods, being responsible for about 90 per cent of the carbon black produced in America.[1] In the case of Fumarex and similar types of carbon black, no precipitating surface is used, the hot gaseous products being passed into settling chambers where the finely divided carbon is removed by filtration or by washing with water. Lampblacks are obtained by a similar process in which liquid and solid hydrocarbons are burnt in a limited air supply without the use of precipitating surfaces.

Another type of carbon is made by the thermal decomposition of hydrocarbons under carefully controlled conditions either in continuous or batch operation. The principles underlying this mode of production of carbon blacks, which include the Thermax and P.33 products of the Thermatomic Carbon Co., are discussed in Chapter 7. Materials, such as petroleum coke, obtained by destructive distillation of organic substances may also be classed under this heading although they bear no relation to carbon blacks in general.

Certain types of black have been produced by exploding a hydrocarbon gas, such as acetylene, in a limited supply of air. Another procedure consists in decomposing hydrocarbon gas or vapors (and also liquid hydrocarbons) by an electric discharge.[2] No information is available as to the extent to which such methods have been, or are being, exploited industrially.[3]

The manufacture of carbon black is confined almost exclusively to the U.S.A., although small quantities are now being made in Canada, Germany, Rumania, Japan, Russia and a few other countries for domestic use. The annual productions of carbon black in the U.S.A., as well as the annual sales, both domestic and for export, for the years 1928-1935 inclusive are listed[4] in Table 50, which shows very clearly the wide-spread use of the channel process.

According to Drogin,[5] 350 million lbs. of black were made in the U.S.A. in 1935, of which 310 million lbs. were prepared by the channel process. The domestic

Total	280,579	283,806	251,539	258,426	261,555	374,468	312,612	387,536

consumption in 1935 included 182 million lbs. in the rubber industry and 17 million lbs. in the printing ink industry, the average price being 4 to 8 cents per lb. with a maximum price of $1.10 per lb. for certain jet blacks. Approximately 35 per cent of all carbon black sold in the U.S.A. is exported, the principal consuming countries being Great Britain, France and Germany.

The main producing areas of the U.S.A. are at present located in the states of Texas, Louisiana, Oklahoma and Wyoming. Of these, the Panhandle district of Texas is by far the most important, about 76 per cent of the total world production being manufactured in that region alone.

DEPOSITION OF CARBON BLACK FROM NATURAL GAS FLAMES BY USE OF COOLING SURFACES

Despite numerous attempts to develop more economical methods of manufacture, the incomplete combustion of natural gas and deposition of the resulting carbon on suitable cooling surfaces still remains by far the most important method of operation.[6] From a chemical point of view the yields obtained, which average 1.43 lbs. per 1000 cu. ft. of natural gas burned or about 4 per cent of the theoretical,[6a] are far from satisfactory but are justified by the high quality of the product and the cheapness of the raw material. In 1935 the price of natural gas employed in gas black manufacture was about 3 cents per 1000 cu. ft.[7]

---

[6] Reviews of carbon black production have been given by Carleton Ellis, *Petroleum Z.*, 1935, **31** (14), 9; *Chem. Abs.*, 1935, **29**, 7595. I. Drogin, *India Rubber J.*, 1935, **90**, 259; *Chem. Abs.*, 1935, **29**, 8249; *Brit. Chem. Abs.* B, 1935, 932. E. Dittrich, *Brennstoff-Chem.*, 1935, **16**, 121; *J. Inst. Pet. Tech.*, 1935, **21**, 210A; *Chem. Abs.*, 1935, **29**, 5631; *Brit. Chem. Abs.* B, 1935, 534. N. Pirozhkov, *J. Rubber Ind. (U.S.S.R.)*, **1936**, 594; *Chem. Abs.*, 1936, **30**, 6900. See also Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[6a] Assuming that the natural gas is entirely methane and that volumes are measured at N.T.P., 1000 cu. ft. of gas should theoretically yield about 33.4 lb. of carbon black.

[7] I. Drogin, *Chem. Met. Eng.*, 1936, **43**, 95; *Chem. Abs.*, 1936, **30**, 3174.

The factors influencing the choice of natural gas are (1) nitrogen content, (2) sulphur content, (3) natural gasoline content, (4) gas pressure, (5) proximity of gas wells to carbon black plant, and (6) industrial and domestic demand for the gas.[8] Nitrogen in high concentrations enormously reduces the yield, a gas of 41.3 per cent nitrogen giving only 0.068 lbs. of black per 1000 cu. ft. Gas containing more than 1.5 grains of hydrogen sulphide (approximately 0.007 per cent by volume), or 30 grains total sulphur per 100 cu. ft. is regarded as dangerous, because of its corrosive action on the burner pipes, although Pidgeon[9] believes that concentrations as high as 1 per cent of hydrogen sulphide have but little effect on the yield and properties of black. Natural gasoline affects the quality, and it has been found more profitable to extract the gasoline rather than to burn it for the production of black.

Pidgeon[9a] points out that although low prices for carbon black result as long as the natural gas supply exceeds the demand, this condition will not always remain so, and eventually more economical means of production must be found. One suggested outlet is the utilization of waste gases from cracking operations since it has appeared that olefins are largely responsible for carbon black formation in pyrolysis operations. Using an experimental channel plant, it was shown that the amount of black obtained from a given volume of propane-butane mixture was greater if the gas was first pyrolyzed (up to 850°C.) to yield aromatic liquids and the residual gases burned, than if the original mixture was burned directly. Thus, the best yield obtained with the untreated paraffin mixture was 4.9 lb. per 1000 cu. ft., whereas the same gas after treatment produced 5.4 lb. per 1000 cu. ft. (of original gas) in addition to about 23 to 25 lb. of light oil formed during pyrolysis.

THE CHANNEL PROCESS

Details of the construction and operation of plants for the manufacture of carbon black by the channel process have been supplied by Allen, Price and Reinbold.[10] In this process, natural gas is burnt with a controlled deficiency of air in burners provided with lava tips of various types. The flame is projected against the underside of standard steel channels, 7 or 8 inches wide, in which the black is collected. The channels are bolted together forming a grid with the channel edges turned up. The grid is suspended by means of cross channels at the ends of which are fitted angles bearing flanged wheels which run on a track and carry the channel grid. The latter is moved continuously in a longitudinal direction with a reciprocating motion over the stationary gas flames. The deposited black is removed from the channels by scrapers and then falls into hoppers from which it is continuously removed by a screw conveyor (or other means) and transported to the bolting and packing houses. The whole arrangement of burners and channels is enclosed in burning houses, usually called hot houses, which are placed in rows 15-20 feet apart, this space or alley being reserved for the conveyors employed for transporting the product to the central packing house. Factories are now in operation with as many as 60 hot houses (operating continuously) per single packing house.

On reaching the packing house, the black is bolted, or sifted, in various ways to eliminate foreign matter and break up the flakes formed on the channels. It is next conveyed to a large bin where the volume-weight relationship is reduced to such a degree that it can be packed in paper bags by a standard screw packer. Handling of the material in bulk has been greatly facilitated by later developments whereby the black is treated in such a way as to give granular pellets of a size passing through a 20-mesh screen but retained by screens of 65-100 mesh. These pellets are agglomerated by special treatment so that the particles adhere firmly to one another and can be handled with very little formation of dust.[11] Moreover, this so-called dustless black has the same apparent density as the hydraulically, or mechanically, compressed product, and is chiefly used in rubber production. It is said that compression of carbon black eliminates practically all danger of fire during handling.

FIG. 77.—Channel Black Plant Under Construction.

Importance of the Flame in the Channel Process. According to Wiegand,[12] the draft conditions in the burner houses need to be adjusted frequently with change of wind and other atmospheric conditions. A good indication of conditions in the house is obtained by observation of the so-called "smoke blanket," which is a blackish haze appearing approximately at the level of the channel irons. If the smoke blanket rises above or falls below its normal level, an adjustment of drafts becomes necessary. The quality of the black has been shown to depend markedly on the type of flame used. Wiegand has stated that a flat flame is essential for a good product, while a round flame furnishes a gray form of black which is not satisfactory for most purposes. (The latter appears to develop at lower temperatures.) For obtaining a flat flame, the bat wing burner, which is slotted, or the fish-tail burner, which has two opposing jets, may be used. Tests made with rubbers compounded with 40 per cent of blacks made with a flat flame and a round flame, respectively, and with diphenylguanidine as accelerator, gave the following results:

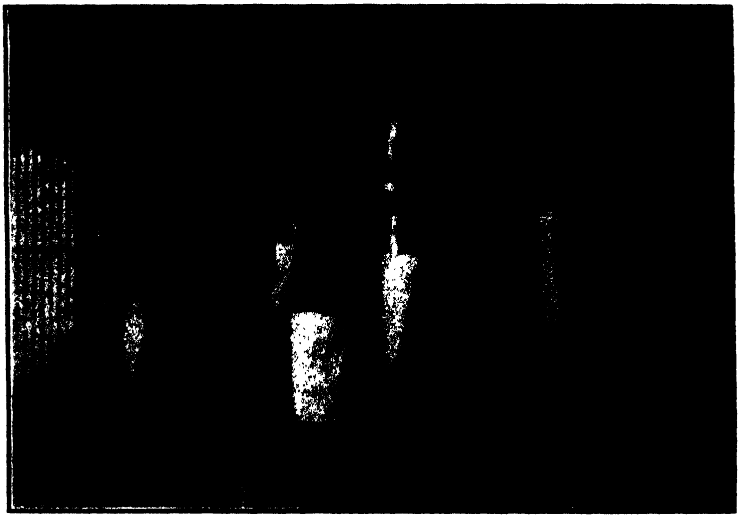
---

[11] A discussion of dustless blacks and the modification of the physical characteristics of blacks will be given later in this chapter.

[12] W. B. Wiegand. *Ind. Eng. Chem.*, 1931, **23**, 178; *Chem. Abs.*, 1931, **25**, 3442.

	Tensile Strength Lbs. per sq. in.	Elongation %
Black from round flame....	3800	580
Black from flat flame......	4700	630

Small scale experiments, described by Wiegand, indicate that the yield of carbon black depends not only on the flame structure but also on the channel height and the rate of flow of gas to the burners. The yields of carbon black obtained from round flames are greatly influenced by relatively slight changes in gas flow, whereas the flat type of flame is hardly affected over a considerable range of gas velocities. A flat flame is, however, more sensitive to channel height than the round flame.



Courtesy Columbian Carbon Co.

FIG. 77a.—Packaging Carbon Black.

Additional factors which have to be taken into account in large scale operation include size and shape of burning house, total gas to be burned in relation to size of house and channel area; spacing, width and reciprocating speed of channels and spacing, angle and accuracy of tip orifices.

Channel height is considered by Pidgeon[12a] to be the most important single variable affecting the properties of channel black. Proper adjustment of this height is essential because rather sharp maxima exist for both yield and quality. The greatest yield obtained in an experimental plant under constant flame conditions, i.e., size of burner tip and gas pressure, resulted with channel settings about intermediate between the lowest height tolerated by the flame and the highest at which any carbon recovery was possible. An approximately straight-line relationship existed between yield and quality, based on the rubber-reinforcing properties of the product. It was suggested that changes in quality of carbon black

[12a] L. M. Pidgeon, *Can. J. Research*, 1937, 15B, 187.

from any one plant may be the result of variations in effective channel height brought about by fluctuations in gas pressure and atmospheric conditions.

Other Surface Impingement Processes. Lewis[13] impinges the hydrocarbon flame on a metallic surface maintained at a high temperature. Radiation from this depository is checked by covering the unproductive areas of the plate with a layer of insulating material. Fireclay, asbestos and ceramic cement are all recommended for this purpose.

According to Guyer,[14] gases obtained in oil cracking, rich in propane and butane, may be subjected to further controlled partial cracking at 675-950°C. and at a contact time of 0.002 to 0.02 minutes to produce olefins. These gases, containing 35 to 50 per cent of unsaturated hydrocarbons, may be decomposed by partial combustion.

PRODUCTION OF BLACKS BY NON-IMPINGEMENT PROCESSES

The incomplete combustion of gaseous, liquid or solid hydrocarbons may be controlled to furnish lampblack, a species of carbon black having properties somewhat different from those of the normal gas blacks. In processes of this sort in which flame impingement on solid surfaces is not employed, the hydrocarbons are burnt with a deficiency of air in flames and the gaseous products of combustion entrain the carbon formed, which is recovered by filtration or water-washing.[15]

In the Lewis process,[16] a product known as Fumarex is produced by the incomplete combustion of natural gas in firebrick-lined furnaces. The mass of flame, which is about 8 feet across, is varied in height according to the grade of black required, the combustion being gauged by the appearance of the heavy blanket of fumes. On leaving the top of the furnace, the fumes pass through a horizontal pipe into the collectors where they are washed by a countercurrent spray of water. By this means, the gas is cooled and simultaneously freed from the finely divided carbon particles which remain suspended in the water and pass with it to large settling tanks provided with conical bottoms to facilitate deposition and removal of the very heavy slurry of carbon black and water. The slurry is passed through a filter press and dried. Fumarex possesses characteristics quite different from those of channel or gas blacks. It is not as black in toptone or in tinctorial power but is much softer and has a clear blue undertone. One of its main uses is in the manufacture of soft rubber goods, such as shoes or hose.[11]

Pidgeon[18] has described a method whereby hydrocarbon gases, such as propane-methane or ethane-propane are thermally decomposed to give yields as high as 60 per cent of the available carbon in the feed by employing a "wall-free" reaction space. A porous refractory tube through which an inert gas may be passed serves for this purpose. The advantage of this type of apparatus is that the reacting gas is unable to come in contact with the walls of the system, so that the deposition of carbon thereon is prevented, and at the same time, an efficient heat transfer between the source of heat and the reacting gases is maintained. The tube was heated to 1300-1400°C. in a gas fired furnace and the rate of diffusion of the inert gas was controlled by varying the pressure difference across the walls of the tube. The black produced in this manner is said to be similar to those of the "soft" type in that it has a high density, low sorptive power, imparts similar resistance to aging and abrasion and accelerates the cure in a rubber stock.

Keller produces carbon black by causing parallel streams of air and gaseous hydrocarbons to flow upward in sheets of one-eighth to one-half inch thickness within a heated unobstructed space, protected from atmospheric disturbances, under such conditions that adjacent streams of gas and air come into contact while maintaining streamline flow. The amount of air used is from 55 to 80 per cent of that required for combustion of the gas. The ratio of the velocities of the gas and air streams is maintained between 1 :0.67 and 1 :2 and the absolute velocities are such that the carbon black, which is formed at the surface of contact, remains in the high temperature zone for 0.05-0.4 second.[19]

FIG. 78.—Plant for Manufacture of Carbon Black by Lewis Wet Process.

Prerau recommends preheating the hydrocarbon material and burning it in open furnaces in a blast of heated air or a mixture of air and gases,[20] and Kingo reports increased yield and better quality by automatically introducing cold air into the flue connecting the condensation chamber with the collecting chamber.[21] Dissociation of hydrocarbons by passage through a layer of live flame at a temperature of 1000-1400°C. has also been proposed.[22] Heid[23] suggests intimately mixing vaporized oil with hot combustion products whereby partial cracking takes place. The gaseous mixture, together with any entrained carbon is removed from the reaction zone and subjected to incomplete combustion.

Hydrocarbons such as ethylene, propane and butane, not explosive by themselves, can be decomposed by ignition of explosive mixtures of the gas with oxygen.[24] The amount of oxygen used should be just sufficient to form the necessary explosive mixture, as an excess will result in complete combustion to gaseous products. The black obtained is particularly suited as a filler for rubber. Acetylene-oxygen mixtures may also be treated in this manner.[25] Mixing steam with the gas and oxygen has also been advocated to give, in addition to carbon black, an exit gas having a composition of hydrogen and carbon monoxide suitable for a feed stock for subsequent conversion into ammonia or methanol.[26]

ACETYLENE BLACKS

Acetylene is used quite extensively for the manufacture of carbon blacks abroad. One of the methods in use at present is based upon the fact that acetylene subjected to a pressure of more than two atmospheres will propagate decomposition throughout the total volume if this is started in one place by an electric spark or other means. Both carbon and hydrogen are recovered in this process and the black resulting is known as acetylene explosion black. It is finely divided and a very pure carbon, but the intensity of color is less than that of the channel carbon.[27]

A purely thermic process of decomposing acetylene has been developed in Canada. Acetylene is dissociated into its elements by heating to the decomposition temperature (800°C.). The black produced is not of an intense nature, but due to its very voluminous properties, it possesses several other extremely valuable characteristics, such as high mechanical absorption, small particle size and a relatively high electrical conductivity.[28]

PRODUCTION OF BLACKS FROM LIQUID AND SOLID HYDROCARBONS

The manufacture of lampblack has been carried out for many years by the incomplete combustion of cheap raw materials, such as creosote, naphthalene or tar oils, the smoky vapors being cooled and treated for the removal of the suspended particles. In general, lampblacks so prepared have physical characteristics markedly different from those of carbon black and cannot compete with the latter in most of its major applications. However, certain types of carbon black adapted for special uses may be produced by burning hydrocarbon oils under controlled conditions though it is doubtful whether truly high grade products can be made in this way. In Russia, black is being manufactured by the incomplete combustion of green oils,[29] the gaseous products being cooled to 50-70°C. and filtered. A material prepared in this way contained 0.38 per cent moisture, 0.04 per cent ash, 1.76 per cent volatile material, and had a volume of 7.28 cc. per gram.[30]

An apparatus somewhat reminiscent of that employed in the well-known channel process is used by Dusek.[31] The fuel (such as naphthalene) is fed to parallel rows of orifices in a multiflame flat burner, directly under a grate-shaped cooler

made up of parallel water-cooled tubes approximately twice the length of the burner and capable of being moved periodically to and fro through the flame. The carbon deposits on the tube-surface and is automatically brushed into the collecting receptacles arranged on either side of the burner. Jakosky[32] has suggested converting solid material, e.g., still residues, gilsonite, or copal resin, into blacks. In his procedure, the material is treated with a solvent (e.g., Diesel oil or alcohol), and after separation from the impurities the solution is subjected to localized high-temperature heating to effect dissociation. Morrell[33] has proposed to carbonize a mixture of finely divided carbonaceous material and an aqueous emulsion of wood- or coal-tar pitch.

PHYSICAL AND CHEMICAL PROPERTIES

The physical and chemical properties of carbon blacks vary considerably, depending upon the processing and type of hydrocarbon gas used. Kaufmann[34] gives a comparison of the properties of acetylene black obtained by the thermal, explosion and channel methods. (See Table 51.) While the channel acetylene blacks are related to the American gas blacks, the thermal acetylene blacks resemble high grade lampblacks, but owing to the high temperature of formation, the properties of these thermal blacks approach those of finely divided graphite.

TABLE 51.—*Comparison of Properties of Carbon Blacks.*

		Acetylene Blacks	
	Thermal	Explosion	Channel
True density	2.05	1.89	——
Resistivity at 2500 lbs./sq. in. pressure, ohms/sq. in.	0.0464-0.035	0.0624-0.0564	0.2180-0.1400
Tinting value (nigrometer)	100	130	140
Microstructure	Loose, spongy structure	Loose, spongy structure	Dense, solid bodies
Absorption of linseed oil, grams/gram of black	5	3.7	2.18
Wetability	None	None	Readily

The purity of the acetylene blacks is quite high, seldom less than 95 per cent.[35] The impurities are usually polymerization products of acetylene, principally aromatics such as benzene, naphthalene, anthracene or phenanthrene (especially in the case of the low-temperature operations), or mechanically introduced substances such as iron[36] or silica. See Table 52.

TABLE 52.—*Impurities in Acetylene Blacks* (*Values given are in per cent*)

Type	Moisture	Volatile	Ether Extract	Ash
Thermic	0.05	1.3	0.02	0.04
Explosion	0.06	1.0	0.05	0.03
Channel	0.38	3.0	0.6	1.0

Day and co-workers[37] have investigated the ash obtained upon combustion of blacks produced from various hydrocarbons. The ashes obtained were white, partially soluble in hydrochloric acid and completely soluble in hydrofluoric acid. Ash values (in per cent) obtained with liquid hydrocarbons are:

Unpurified acetylene and natural gas resulted in blacks with an ash content of about 0.5 per cent, whereas values as low as 0.01 per cent were obtained using acetylene of a better quality.

A carbon black, Carbomet No. 3, made from Transylvania natural gas, has been found to be satisfactory for rubber compounding. Waldner[38] believed this Rumanian black is equal, and in some respects even superior, to American gas blacks. Table 53 gives comparative values for the Rumanian product and Dixie Ordinary, an American gas black.

TABLE 53.—*Properties of American and Rumanian Gas Blacks.*

	Carbomet No. 3	Dixie Ordinary
Apparent sp. gr.	0.160	0.110
True sp. gr.	1.78	1.76
Fineness (in Chancel degrees)[a]	20	20
Coloring power	Good	Good
Acetone extract	0.3	0.26
Ash	0.058	0.073
Oil absorption, cc./100 g.	230	250
Iodine adsorption, mg/100 g.	257	274
Methylene blue adsorption, mg./100 g.	49.54	43.60
Diphenylguanidine adsorption	18.70	15.88

[a] The Chancel method is an empirical test for estimating the degree of fineness, usually employed in sulphur determinations. The procedure used is to shake a 5 g. sample in a so-called "Sulphurimeter" or "Sulphimeter" (a long, graduated glass-stoppered cylinder) with anhydrous ether and to measure the scale division reached by the suspended material after settling. Consult V. Villavecchia. "Treatise on Applied Analytical Chemistry," (Translated by T. H. Pope), P. Blakiston's Son & Co., Philadelphia, 1918, I, 112, for details.

Oshima, Fukuda and Akashi[39] investigated the ignition temperature and rates of combustion of carbon black alone and impregnated with 5 per cent solutions of various inorganic substances. They find that the ignition temperature is lowered, and report the following values: original carbon black 508°C., washed black 497°C., carbon black and potassium hydroxide 278°C., carbon black and potassium carbonate, 286°C., and carbon black and potassium chloride 403°C. The combustion velocity was practically unaffected by the presence of the added inorganic materials.

X-ray diffraction patterns of carbon black, made with strictly monochromatic radiation, show clearly the existence of single graphite layers and indicate a heterogeneous mixture of these with graphite crystals several layers thick. (See Fig. 82.) According to Warren[40] carbon black comprises a continuous series of particles extending from the mesomorphic to the crystalline state.

It is generally considered that the property of blackness is intimately connected with particle size and that increasing color intensity runs parallel with decreasing particle diameter. The evidence for this belief, though more or less indirect and circumstantial, is considered by Wiegand and Snyder[41] to be quite convincing. Thus, from measurements of heats of wetting, Hock[42] found a correlation between increasing specific surface and increasing tinctorial power, as measured in 1 per cent mixtures of the black with lithopone. Moreover, Goodwin and Park[43] carried out experiments on the reinforcement of rubber by means of a high color black (Super Spectra) and concluded that the effect of this black indicated a smaller particle size than that of a standard rubber black. A similar conclusion has been reached from estimations of particle size by indirect methods. It is interesting to note also that color intensity is also intimately related to *oil absorption*, as can be seen from Table 54 in which the oil absorption figures refer to the amounts of pale grinding linseed oil required for a given weight of black to produce a product of fixed viscosity, while the colors were observed by the nigrometer.[44]

Fig. 82.—X-Ray Diffraction Pattern of Carbon Black. Taken with copper *Kα* radiation.

Table 54.—*Oil Absorption of Carbon Blacks.*

Blacks	Color Intensity	Oil Absorption, Gal./100 lb.
High color	38.3	275
Medium color	29.8	196
Low color	26.9	158
Low rubber	23.8	127
Rubber color	18.3	100

In view of the importance of particle size on color intensity, it is only to be expected that the production of high-intensity blacks necessitates a more refined technic and a more careful control of operating conditions than is needed for blacks of inferior color. The conditions necessary for the manufacture of the best color blacks include a higher ratio of secondary air to hydrocarbon gas, more burning tips and closer channel settings. As a result, the yield of high color black from a given volume of gas is reduced to only five per cent of that normally obtained in the production of ordinary blacks.

The intensity of color is greatly influenced by vibration, compression and mechanical action of various kinds so that compaction of carbon blacks by agitation in the collecting bin or by compression at a later stage, must be avoided as much as possible.[45] Moreover, special care should be exercised in packing to minimize vibration in transit. Wetting down of high-intensity color blacks followed by drying to eliminate entrained air is also harmful. Wiegand and Snyder suggest this may be due to the removal of a cushion of entrained air which served to inhibit the natural adhesion or flocculation of the particle.[46]

The rise in oil absorption values of carbon blacks of increasing color intensity has proved a troublesome factor in their industrial applications since it results in greater difficulties in grinding and, subsequently, a marked tendency towards reagglomeration, seeding or flocculation. As a result of this difficulty, it has been impossible formerly to take full advantage of the improved color developments. An intensive study directed towards the improvement of surface conditions such as to provide lower interfacial tension between the black and the common dispersion vehicles, has led to the development of special blacks, such as Neo-Spectra. These, while registering a marked increase in color intensity when incorporated in linseed oil vehicles, show at the same time oil absorption values and ease of dispersion comparable with those of blacks much lower in the color scale. In a similar way it has been found possible to modify the surface characteristics of blacks so as to render them more useful in nitrocellulose lacquer media because of the possibility of employing higher concentrations of black with the resulting improvement in color and gloss.

The dispersion of lampblacks has been studied by Krauze, Pamfilov and Rosljakova[47] who found that this property varied with the medium taken and was in no case equivalent to dispersion to primary particles. The dispersing effect of different media was shown to vary with different preparations of lampblack.

MODIFICATION OF PHYSICAL CONDITION OF CARBON BLACK

Because of its extremely fine state of subdivision, the handling of carbon black in bulk presents serious difficulties, especially as regards dust formation. For this reason considerable attention has been directed towards the preparation of the so-called dustless blacks, which are essentially granules of carbon black so compounded that the individual particles adhere to one another with sufficient tenacity to render the granule mechanically stable.[48] This object is achieved by Billings and Offutt[49] by subjecting flocculent carbon black to turbulent agitation in the dry state in a drum equipped with a bladed stirring device and a more slowly moving scraper to prevent accumulation of carbon on the walls of the drum. By means of this treatment the black is agglomerated into relatively tenacious spherical granules having smooth, non-adherent surfaces, with an apparent density of more than 18 lb. per cu. ft. Burger[50] achieves similar results by passing the black between rollers. The thin plates which result are similar in appearance to fish scales and can be very conveniently employed in rubber compounding.

Another procedure[51] consists in introducing droplets of a suspension of carbon black in a liquid medium into an atmosphere in which the droplets are partially dried while they remain suspended. Thus, carbon black is dispersed in water, which may contain both protective and surface tension depression agents, and the suspension is allowed to impinge onto the surface of a rapidly rotating horizontal disc mounted near the top of a tall cylindrical drying chamber through which passes a counter-current of air. In a modification of this method, carbon black, mixed to a stiff paste with a volatile liquid such as ethyl alcohol or benzene, is fed to a rotary apparatus in which it is broken into fragments, the latter being then rapidly dried by exposure to gases at temperatures of the order of 200-260°C.[52]

---

[46] It should be noted that in the Lewis process, which furnishes a low intensity black (blue undertone), the wetting process serves two important purposes, freeing of occluded matter and reducing the volume-mass ratio.

[47] K. E. Krauze, A. V. Pamfilov and E. N. Rosljakova, *J. Gen. Chem., U.S.S.R.*, 1935, **5**, 438; *Brit. Chem. Abs.* **B**, 1935, 791; *Chem. Abs.*, 1935, **29**, 5327.

[48] The products obtained by these treatments are not of high intensity blackness, according to J. W. Snyder *(loc. cit.)*. In many cases, for instance, as a filler for rubber, the degree of color is of minor importance, the principal requirement being the mechanical stability of the material.

By moistening carbon black with about 40 per cent of water, sufficient to form a pasty, friable mass and from which the water is evaporated by spraying into a heated atmosphere at about 400-500°F., Grote[53] produces small round particles of carbon black with reduced dusting and soiling properties. These particles have an apparent density greater than that of the loose carbon black, and they crush easily when mixed with such materials as rubber or wax. Another method of agglomeration is to moisten the black with a volatile liquid (alcohol, water, gasoline or acetone) and mold the pasty mass into thin sheets. The latter are subdivided into small fragments and dried.[54]

The preparation of dustless carbon black has been discussed by Platonova,[55] who recommended briquetting an emulsion of 200 grams black, 24 grams sapropelite tar and 50 cc. water and drying the granules at 105°C. for three hours. Similar results were achieved by briquetting a mixture of 200 grams carbon black and 100 cc. of a 5 per cent aqueous solution of dextrin and drying for 4 hours. Both of these products gave satisfactory dispersion tests in 2 per cent aqueous ammonia.

Stable dispersions of carbon black in water are obtained by Tucker[56] in the presence of 2-6 per cent (based on the carbon black) of a soluble salt of a compound obtained by condensing a sulphonated aromatic hydrocarbon with formaldehyde. Another agent of this type is obtained by reacting 1 mole of formaldehyde with about 2 moles of β-naphthalene-sulphonic acid. The dispersing properties are improved by the addition of 1 to 10 per cent of an alkaline earth naphthenate. This is effected by dispersing the carbon black in an aqueous solution of an alkaline naphthenate, adding an alkaline-earth salt, washing and drying.[57]

According to Wiegand[58] channel blacks are improved both in blackness and workability by allowing the black to remain in free contact with the atmosphere of the burner house at 300 to 1000°C. This treatment causes partial oxidation and is said to furnish a material with a color index greater than 25 and a ratio of color index to oil-absorption index in excess of unity.[59] Damon,[60] however, prefers to heat carbon black in a rotating drum at not more than 540°C. in a current of gas containing oxygen. This treatment is said to increase the oxygen content of the black and thereby improve its color. An improved form of black is said to result

also by subjecting the material to the action of hydrogen at 350-500°C. and 5 to 500 atmospheres pressure for $\frac{1}{4}$ to 10 hours.[61] To improve the oil-adsorption power of carbon black without diminishing its color intensity, Grote[62] recommends attrition in an atmosphere of carbon dioxide at 200-425°C. for 5 to 15 hours.

Another method of improving the quality of thermal blacks has been described by Frenkel.[63] Treatment is effected by injecting a mixture of the material with water into a heated gaseous medium, such as carbon dioxide or nitrogen, under a pressure and at a temperature such that steam is instantaneously generated and the carbon black is disintegrated into very fine particles of a size less than 1.0 micron. Eagles[64] proposes to inhibit the agglomeration of the fine particles of black suspended in the gaseous products of combustion by passing the gas and suspended material through a screen into a relatively cool stream of inert gas.

INDUSTRIAL APPLICATIONS OF CARBON BLACK

The characteristic physical properties of carbon black, which render it of such great technical value, are intimately associated with its extremely minute particle size, the latter being well below the resolving power of the best microscopes. Indirect measurements indicate a value of 0.025 micron for the diameter of particles of high-intensity color blacks,[65] while the particle diameter of standard rubber carbon blacks is about 0.06 micron by the ultramicroscopic count procedure.[66] In this connection it has been stated that the average particle size of the rubber black "Micronex" is of the order of 0.15 micron.[67] Irrespective of the absolute value of the diameter, there is good evidence to believe that the wide variation in physical properties (such as color, tinting power, adsorptive power) displayed by various types of black are mainly dependent on differences in particle size. Such variations in physical characteristics have an important bearing on the possible industrial applications of individual blacks.

Use of Carbon Black in Rubber Manufacture. The most important application of carbon black is in the compounding of rubber whereby the latter's tensile strength is doubled and its resistance to abrasion quadrupled.[68] In 1935, 182 million lbs. of carbon were consumed by the rubber industry in the U.S.A., about 3.3-11.9 lbs. being used in the production of a single tire depending on its size and design.[69]

Another important characteristic of blacks is their adsorptive power, which is usually measured with such substances as diphenylguanidine, methylene blue or iodine. Blacks with high adsorptive power, such as channel blacks, have the property of retarding the curing rate of rubber stocks probably by adsorptive removal of the organic accelerator. On the other hand, materials of low adsorptive power, such as the thermal blacks, do not effect retardation of cure. The question of the adsorptive power has been discussed by Wiegand and Snyder[70] who have concluded that the diphenylguanidine adsorption test correlates well with the rubber-curing behavior of broad classes of carbon black in organically accelerated mixes but the correlation is less satisfactory in the case of Micronex, a standard rubber black.

It has been stated that rubbers having the highest stiffening, tensile properties and resistance to tear and abrasion are obtained by the use of channel blacks whereas, the thermal black, P.33, is used when softness and pliability are desired.[71]

A special black which is suited for use in rubber compounds has been prepared by Odell.[72] He treats a finely divided black produced by the thermal decomposition of hydrocarbon gas or carbon monoxide with the vapors of a rubber compounding catalyst, such as zinc or zinc oxide at about 700°C. In this manner, particles of very minute size, each consisting of a nucleus of pure carbon surrounded by a thin film of adsorbed catalyst, are obtained.

Carbon Black in Manufacture of Printing Inks. The second ranking industrial application of carbon black is in the manufacture of printing inks, compounded of varnish, oils and carbon black.[73] The latter is well known as a pigment capable of providing sufficient opacity in concentrations small enough to preserve the free flowing properties of the vehicle. The consumption of carbon black in the printing ink industry in 1935 amounted to about 17 million lbs., 1 lb. of black being sufficient to print about 4,000 pages of news print. The intensity and strength of the black color displayed by carbon black were mainly responsible for its introduction and rapid development in the printing ink industry, with the result that the older type of carbon pigment, lampblack, has now almost been entirely displaced, although in a few instances mixtures of the two may be employed. However, when a variety of blacks are inspected, that showing a blue-black tone is almost invariably the one selected as constituting a strong full black. Since carbon by itself has more of a brownish tint, the addition of a toning agent, usually a blue type dye is necessary. The latter is especially practiced in the better grade inks in order to overcome a brownish tint apparent in a straight carbon black composition. In this connection it is necessary to differentiate clearly between the color of the black, by which is meant the intensity and tone of the sensation of blackness as determined visually by experienced observers, and the tinctorial strength of a black, which is a measure of its ability to impart color (blackness) to a fixed amount of a white pigment. It has been shown by Wiegand and Snyder[74] that in a series of carbons of increasing color intensity there is a maximum in tinctorial strength at a point well below the highest color values.

Other Uses of Carbon Black. Considerable quantities of carbon black are used in the manufacture of paints and varnishes, and here again the surface properties of the black are of prime importance. The high adsorptive power associated with small particle size has been put to advantage in the improvement of insulating oils, by removing substances harmful to the electrical properties.[75] Consumption of carbon black as a coloring and reinforcing material and as a filler in such products as phonograph records and typewriter ribbons is decreasing, but, later applications in the manufacture of automobile brake bands and in the construction of dark-surfaced highways[76] and as a filler in the manufacture of carbon papers[77] are said to have commercial possibilities.

The several unique properties found especially in the thermic acetylene blacks make it possible for them not only to compete with but actually to replace cheaper blacks in certain fields.[78] In the manufacture of dry cells, thermic acetylene black is employed in connection with pyrolusite (manganese dioxide) and graphite for depolarizing purposes, due to its highly graphitic character and its extreme porosity. which enables a high absorption for the electrolyte. Because of its absorptive capacity, it is used as a filler in liquid oxygen explosives competing successfully with cheaper materials such as coal and cork fillings.

EVALUATION OF CARBON BLACKS

The applicability of a carbon black for any particular purpose can in general only be decided by a practical test carried out under conditions approaching large scale operation. Thus, those products intended for use as fillers in rubber are tested by actual rubber reinforcement tests, the resulting mix being subjected to examination for the determination of its mechanical characteristics, and resistance to abrasion and aging. Similar practical tests have been evolved in other industries, such as the printing ink industry, in which special types of black are needed.[79]

In addition to methods of examination just mentioned, there are a number of physical and chemical tests which are useful. Chemical tests include determinations of moisture, ash and extractable organic material.[80] The latter estimation is usually carried out with boiling acetone in an Underwriter's apparatus. Benzene is said to be a better extractant since it causes less penetration of the black through the fibers of the extraction thimble and is also cheaper.[81] It appears doubtful, however, whether this test has any practical significance as regards the behavior of the black in manufacturing operations.

[81] Private communication from Mr. C. C. Boardman, Thermatomic Carbon Co.

The importance of the adsorptive power of carbons, particularly in rubber manufacture, has already been discussed. For the determination of this property, diphenylguanidine in alcoholic solution is often used.[82]

Barron[83] has described a method for this determination based on the fact that if carbon black is shaken with a mixture of polar and non-polar liquids (benzene and water), it is always retained in the non-polar layer after separation. By titration of the latter the amount of iodine, phenol or benzoic acid adsorbed from the binary liquid system can now be ascertained, and by means of the distribution coefficient, the adsorption from the non-polar liquid can be calculated. The method can also be applied to the study of the effect of dispersed rubber upon the adsorptive power of carbon black for phenol and benzoic acid; the presence of 1 per cent of rubber in the benzene phase markedly reduces this.[84] It has been observed by Lemcke and Hofmann[85] that an acetylene black obtained by impingement on a cooled copper surface has an adsorptive power towards carbon tetrachloride vapor very much inferior to that of several active carbons of commercial grade.

The precautions necessary in the measurement of the color and tinctorial strength of carbon blacks have been discussed by Wiegand and Snyder.[86] They concluded that visual examination is more sensitive than the present instrumental color-testing devices and that further refinement in optical photometry is essential before the visual estimation of color differences is likely to be superseded. The importance of oil absorption values for high intensity blacks to be used as pigments in liquid vehicles has already been discussed. This property is defined by the amount of liquid vehicle required to furnish a mixture of definite viscosity when incorporated with a unit weight of carbon black under standardized conditions.[87]

Chapter 9

Transformation of Hydrocarbons by Electrical and Other Special Forms of Energy

Two applications of electrical energy for various conversions of petroleum hydrocarbons which are outstanding are (a) voltolization and (b) the arcing treatment of hydrocarbons to make acetylene. Voltolization undoubtedly increases the viscosity index, that is to say, it flattens the viscosity-temperature curve and tends to decrease the pour point of an oil, as has been shown by Nash and his associates.

One of the routes to greater development of chemical products from petroleum and especially petroleum gases or natural gas is that via acetylene, a very reactive hydrocarbon from which, for example, acetaldehyde, acetic acid and vinyl resins can be rather readily produced.[1]

THE ELECTRIC ARC

The decomposition of hydrocarbons in the low-tension arc and also in the high-tension electric discharge (spark discharge) results in the production of hydrogen, carbon and acetylene, the latter owing its formation to its increasing thermodynamic stability with rising temperature. In addition to acetylene, considerable proportions of olefin and diolefin hydrocarbons, including ethylene and butadiene, may also be formed particularly when the time of contact with the arc is lower than that required for optimum acetylene production.

In the case of methane, Bozhko and Orshanskii[2] noted that the low-tension arc favored acetylene formation whereas carbon and hydrogen production was promoted by the high-tension arc. Maximum cracking efficiency resulted when the initial gas contained 15 to 20 per cent methane. The rate of gas flow did not influence the character of the reaction although an increase in the rate did diminish energy consumption.

Although the electrical disintegration of methane and its immediate homologues, which are abundantly available as natural gas, has been studied mainly from the viewpoint of preparing acetylene, it is interesting to note that appreciable amounts of olefin hydrocarbon gases are formed by the action of the low-tension arc on some of the heavier hydrocarbon oils. Thus, Fester, di Filippo and Patrone[3] found that the action of an iron arc on kerosene resulted in a gas containing 27.5-35.7 per cent of ethylene and 1.0-4.2 per cent acetylene, while a copper arc gave a gas having 46.7 per cent of ethylene and 7.9 per cent acetylene. When a carbon arc was used, very much more acetylene was formed, the gaseous product containing 34.0 per cent ethylene and 25.5 per cent acetylene. These investigators believed that electric arc cracking is better for the preparation of olefins for synthetic purposes than pyrolysis. Riedelsberger[3a] caused a film of liquid hydrocarbons to flow down the inside of the wall of an arc furnace in which the arc burns in a stream of hydrogen or in a gas consisting mainly of hydrogen.

---

[1] For the production of acetaldehyde and acetic acid from acetylene, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, 1934. Vinyl resins from acetylene are described by Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935. See also Chapter 28, this text.

[3] G. A. Fester, J. di Filippo and B. Patrone, *Rev. facultad quim. ind. agr., Univ. nacl. litoral*, 1932, 2, 130; *Chem. Abs.*, 1933, 27, 5954.

The decomposition of heavy oils in the presence of a low-tension arc has also been described by Gobert,[4] who obtained by this method a gas possessing 35-40 per cent each of acetylene and hydrogen, 5-10 per cent of ethylene and its homologues and some methane and nitrogen. For the production of 1 cubic meter of gas containing 40 per cent acetylene, about 800 g. of oil were required and the energy expenditure was 3.5 kw. hrs.

Baumann, Schilling and Stadler[5] subject waste gases from cracking or hydrogenation operations to the action of a number of low-tension electric arcs in succession with inter-stage separation of acetylene between each arc. The series of arcs is operated so that the energy supply (per unit volume of gas treated) is higher than that in the preceding one and the acetylene concentration in the gas at any stage is greater than that in the one immediately preceding. It has been proposed to use an electric arc struck between a hollow electrode and the wall of the reaction vessel as counter-electrode, the contact point of the arc on the hollow electrode being quickly moved by mechanical or magnetic means.[6] Carbon deposition apparently is lessened when the striking points of the arc are caused to move rapidly on the surfaces of both electrodes. It is reported that a gas consisting mainly of propane yielded a gaseous product containing 14-16 per cent acetylene by this method. A low tension arc of 2 mm. length may be employed and the energy density maintained at about that at which a loss of material, exceeding the normal wear and tear of the electrode substance, commences.[7] Eisenhut, Stadler and Baumann[8] recommend that an energy consumption of at least 2 kw. per sec. per cc. of arc space be employed. In this instance not only gases or vapors of paraffins and olefins serve as raw materials but also fine suspensions or mists of tars or oils in such hydrocarbons.

It is well known that considerable carbon formation takes place during the electrical disintegration of methane, or similar hydrocarbons, and is suppressed by dilution of the hydrocarbon gas with hydrogen. This dilution with hydrogen prior to electrical treatment is achieved, by Baumann,[9] by cracking of the hydrocarbon gases to convert them partly into hydrogen and liquid hydrocarbons. After separation of the latter, the residual gases are passed, with addition of fresh raw material if necessary, through an electric arc for the production of acetylene. Fischer and Peters[10] subject a mixture of methane, or other hydrocarbons and at least an equal amount of steam to the action of an electrical discharge at very low pressures, e.g., 80 mm.

The simultaneous generation of acetylene and high grade carbon black has been disclosed by a number of workers although somewhat different procedures have been recommended. In the process of Baumann, Stadler, Schilling and Bückert[11] a gas rich in methane is first subjected to electrical arc treatment so that carbon black is formed from part of the gas. After removal of the black and unsaturated hydrocarbons formed, the resulting gaseous products are preheated and then passed through a second arc for acetylene manufacture. Eisenhut, Schilling and Baumann[12] suggest that after electrical treatment the gas and carbon black issuing from the arc space be passed, in a whirling motion, directly into a large cooled free space in such a way that the solid remains suspended in the gas and is prevented from being deposited on the heat-conducting surfaces. After the cooling operation the black is separated from the gases. . In the decomposition of mineral oils,[13] the arc is located beneath the surface and fresh material is introduced at such a rate that a 5-15 per cent suspension of carbon in oil is continually withdrawn.[14] The production of carbon blacks by electro-thermal dissociation of liquid hydrocarbons has been described also by Jakosky.[15]

Transformation of hydrocarbons under the action of a luminous arc produced by a direct-current generator has been disclosed by Baumann, Krapp, Stadler and Speidel.[16]

Gases from the electrical decomposition of hydrocarbons contain, in addition to acetylene and hydrogen, varying proportions of highly unsaturated compounds, such as diacetylene, allene, allylene and butadiene. Removal of these impurities is effected either by passage over an adsorbent such as active carbon or silica gel[17] or by cooling the gas mixture to about —70°C. to condense them.[18] According to Zobel and Reich,[19] treatment with a chloride or an acid having a polymerizing action, as, for example, aluminum chloride or sulphuric acid, is effective in the removal of unsaturated impurities. In other instances acetylene is absorbed by washing with a solvent, such as ethyl alcohol or acetone, at a temperature below —81.5°C., the triple point of acetylene.[20] After absorption, the residual gas is applicable for use in the destructive hydrogenation of distillable carbonaceous substances.[21]

Lead alkyl compounds are said by Sullivan and Diwoky[22] to be produced by the action of a high-tension electric arc of about 250,000 volts on liquid or gaseous

hydrocarbons in the presence of lead. Thus, the arc may be struck between lead electrodes immersed in the hydrocarbon and the lead alkyl compounds recovered in the pure state by fractional distillation, or as a solution in the hydrocarbon liquid in which they are formed. Dispersions of metals in hydrocarbon oils are prepared similarly by Arnold[23] using a high-frequency current.

Using zinc electrodes, Petřik[24] obtained a gas rich in hydrogen by the action of the electric arc or spark in water vapor. When carbon electrodes were used, water gas (50 per cent hydrogen and 50 per cent carbon monoxide) was produced. With the latter electrodes, ethyl alcohol and petroleum gave gases having the compositions shown in Table 55.

THE SILENT ELECTRIC DISCHARGE

Silent discharge[25] is the term used to designate the low current discharge which takes place between electrodes, separated by gaseous (or non-ionized liquid media), at high potentials but below those at which sparking occurs. The current is usually alternating and the discharge in gases at about atmospheric pressure varies in appearance according to the circumstances but in all cases the current passing is lower than when true sparking takes place. In the silent discharge in an ozonizer, the electrodes are both separated by a glass dielectric from the gaseous medium and the current passing is very small. When one or both electrodes are in direct contact with the gas, the so-called semi-corona and corona discharges result and the current passing may be considerably greater. When the gaseous medium is at relatively low pressure the phenomena of the gaseous discharge tube appear and in the resulting glow discharge the current density may be high owing to the increasing production of electrons at the lower pressures. According to Peters,[26] the low pressure glow discharge in gases approaches more nearly to an arc, as regards its chemical action, than to the silent discharge. Peters has also discussed the action of the different types of discharge arising from the use of various pressures of the gaseous medium and different potentials, densities and frequencies of the current employed.

The chemical action of the silent discharge is complex and depends on numerous factors including pressure, potential and frequency. Subjection of hydrocarbons to such electrical treatment results in (1) dehydrogenation (except with acetylene) the degree of which increases with the degree of saturation of the material treated, (2) rupture of C-C bonds particularly in long-chain hydrocarbons, and (3) polymerization of unsaturated hydrocarbons. In many cases all these reactions take place either simultaneously or in stages so that a complex mixture of reaction products results.

Paraffin hydrocarbons may undergo dehydrogenation or fission of the carbon chain or more complicated molecules may be formed by simultaneous polymerization and dehydrogenation.[27] According to Vanier de Saint-Aunay,[28] methane yields hydrogen, ethane, ethylene, acetylene and a small quantity of unsaturated liquid hydrocarbons. The basic reaction is considered by this investigator to be dehydrogenation to active radicals which condense to ethane, the latter being further dehydrogenated to ethylene and acetylene. In the glow discharge at liquid air temperatures, methane was found by Brewer and Kueck[29] to undergo almost complete conversion into ethylene and hydrogen. Decomposition of methane by the glow discharge has also been investigated by Kobozev, Vasiliev and Galibraikh.[30] They report that about 1.5 per cent of methane was transformed into olefinic and acetylenic hydrocarbons in the presence of aluminum, copper, zinc, lead or iron. However, with mercury electrodes under the same conditions the conversion of methane was 5.2 per cent, which could be increased to 14 per cent by the use of intermediate mercury electrodes or by warming the latter. The effect was ascribed to activation of the mercury vapor which imparted its energy to the methane molecules.

The products obtained by the action of the silent electric discharge on ethane and the higher paraffins consist of hydrogen, and paraffins and olefins of both higher and lower molecular weights than that of the original hydrocarbon. Thus, hexane furnished gases including propane and propene as well as a considerable amount of liquid containing hexene-1, higher pâraffin hydrocarbons of 9 to 12 carbon atoms and also cyclic hydrocarbons.[31] When ethane was passed through a glow-discharge, hydrogen and a resin were formed, indicating a process of decomposition followed by polymerization.[32] The formation of higher hydrocarbons from paraffins is an important characteristic of the silent discharge and may take place either by dehydrogenation followed by polymerization of the unsaturated intermediate, or directly by simple doubling of the paraffin molecule to give an ion cluster followed by elimination of hydrogen. The latter mechanism was suggested by Lind and Glockler,[33] who obtained a mixture of octanes and octenes from butene. Whatever the mechanism of the change, liquid paraffin hydrocarbons, when subjected to the action of the silent discharge, undergo an increase in viscosity and molecular weight with simultaneous evolution of hydrogen.[34] This increase (in viscosity and molecular weight) is cumulative, the effect becoming greater with time of contact and also with the power input. The optimum frequency is reported by Tarasov[35] to be 500 cycles per second. Treatment of higher paraffins, such as dodecane, with a silent discharge at 7500 volts and a frequency of 1000 cycles for 6 hours is said to result in the formation of 23-28 per cent of higher molecular weight hydrocarbons.[36] Olefins such as octene, however, yielded up to 60 per cent of polymers.

It appears that unsaturated hydrocarbons not only undergo extensive polymerization but also dehydrogenation and redistribution of hydrogen atoms. Under conditions favoring the formation of primary products, namely at low temperatures and with rapid withdrawal of the reaction products from the discharge zone, Mignonac and Vanier de Saint-Aunay obtained 1-butene and 1-hexene from ethylene and straight chain trimers from acetylene.[37] Later work of de Saint-Aunay[38] indicated that the three main reactions taking place in the case of ethylene were (1) polymerization to butene and hexene, (2) dehydrogenation to acetylene and hydrogen and (3) hydrogenation by the liberated hydrogen to ethane, butane and other paraffins. Balandin, Eidus and Zalogin[39] subjected ethylene to the action of a high-frequency discharge of 5-8 watts at 15,000 volts. In a closed system the products consisted of a thick oil having a molecular weight of about 500 and a gas containing hydrogen and paraffin hydrocarbons. On the other hand, butadiene and acetylene were formed in a circulatory system. The proportion of butadiene was dependent on the rate of circulation and on the proportion of hydrogen mixed with the ethylene prior to treatment. A chain mechanism was suggested by these investigators to explain the results. Polymerization of several liquid olefin hydrocar-

Aromatic hydrocarbons were also transformed by the silent discharge, the products including hydrogen, acetylene, polynuclear aromatic hydrocarbons and insoluble solid shellac-like bodies. The decomposition of benzene vapor at 100°C. was investigated by Vanier de Saint-Aunay.[41] He obtained a gas, containing 33 per cent acetylene and 52 per cent hydrogen, as well as a liquid mixture from which biphenyl and two isomeric dihydrobiphenyls were isolated. It was believed that polymerization to dihydrobiphenyl first occurred and this was subsequently dehydrogenated to biphenyl. In addition, depolymerization to acetylene also took place accompanied by hydrogenation of the acetylene to ethylene and ethane by hydrogen liberated in the biphenyl formation. Evidence for the production of biphenyl, biphenylene and more complex products from benzene in the electrodeless discharge was secured by Hiedemann.[42] The decomposition of benzene vapor at low pressures in the electrodeless discharge has also been examined spectroscopically by Harkins and Gans[43] who found indications of the transient existence of C^+ ions, atomic carbon and hydrogen and "CH and C_2 molecules." insoluble solid of undoubtedly high molecular weight and having a composition corresponding to $(CH)_n$ was formed. The production of an insoluble solid material from this aromatic by the action of the brush discharge[44] and also by the Tesla discharge[45] has been observed.

Toluene vapor behaved in the silent electric discharge (at about 115°C.) in a manner similar to that of benzene, the products including a gas containing 58 per cent hydrogen, 10 per cent acetylene and its homologues, 8 per cent ethylene, 4 per cent ethane, 14 per cent methane, 3 per cent higher olefins and liquid products from which 1,2-diphenylethane (bibenzyl) was isolated.[46] In the Tesla discharge, toluene furnished a shellac-like substance as well as an aromatic liquid, from which Austin and Black[47] recovered 1,2-diphenylethane and 2,2′-dimethylbiphenyl. Under similar conditions, benzene and deuterium oxide (in the presence of platinum black) reacted with partial replacement of hydrogen (in the aromatic) by deuterium.[48] No change was observed in the absence of a catalyst or when ordinary water was substituted for deuterium oxide. The formation of gaseous products from toluene and several other alkyl benzenes in the corona discharge has been investigated by Linder and Davis.[49] They found that the yield of gas (under analogous conditions) increased with increasing molecular weight but diminished with increasing centralization of the molecule and with increasing proximity of the substituted groups in the benzene nucleus.

Razumov[50] reports that when a mixture of benzene, ammonia and oxygen is passed through a high-frequency high-tension electromagnetic field, there are formed aniline, diphenylamine, phenol and water. By maintaining the total gas pressure at the maximum conductivity of the medium, Kleinschmidt[51] produced a direct oxidation of benzene to phenol by air or carbon dioxide. He also polymerized benzene to biphenyl and oxidized and polymerized naphthalene. Working voltages of 1000 to 2000 volts (alternating current) were employed; and pressures less than 10 mm. of mercury were used.

INDUSTRIAL APPLICATION OF THE SILENT ELECTRIC DISCHARGE IN THE MANUFACTURE OF LUBRICATING OILS

An important industrial application of the action of the silent electric discharge on hydrocarbons is in the manufacture of synthetic lubricating oils, the so-called Electrion and Voltol oils, which are characterized by very low viscosity-temperature coefficients, stability to heat and oxidation, greater oiliness than straight mineral oils and good emulsifying properties.[52] This development originated from the observation of de Hemptinne that oils increased in viscosity under the influence of the silent discharge.[53] The apparatus employed consisted essentially of a horizontal cylindrical rotating drum with scoops around the inside periphery, the latter causing the oil contained in the drum to drip continuously over the electrodes located in the center of the apparatus.[54] The initial raw material was a 50 per cent fatty oil-mineral blend and during the electrical treatment the mineral oil content was increased until the final product contained only about 15 per cent of fatty oil.

[53] The investigations of this pioneer in conjunction with the Belgian firm of Cavel et Roeglers led ultimately to the commercial production of the Electrion oils in Ghent in 1912. The Ghent factory was taken over in 1914 by the Germans, who later erected a factory at Potschaffle where 1650 tons of lubricating oil for aeroplanes were produced in 1918. At the end of the World

Details of one method for the preparation of Voltol oils have been given by Isom.[55] In this process, owing to the slow voltolization of straight mineral oils, various vegetable and fatty oils, such as rape-seed, cotton-seed or fish oils, were first treated until they attained maximum viscosity after which 50 per cent of mineral oil was slowly added with continuous treatment until the viscosity approached 40° Engler at 100°C. The electrical treatment was carried out in a converter[56] at about 80°C. under a pressure of 60-65 cm. of mercury with no hydrogen initially present, the current used being 23 amperes at 4600 volts and 500 cycle frequency. Voltol oils were also manufactured by a method in which operations were conducted in an atmosphere of hydrogen.[57] Again, fatty oils were the starting materials, being gradually diluted with mineral oils during the electrical treatment until the final product, having a viscosity of 90° Engler at 50°C., contained 90 per cent mineral oil.[58]

The mechanism of voltolization has been the subject of a number of investigations. Nernst[59] concluded that dehydrogenation and polymerization of the unsaturated residues were the main reactions resulting from the electronic and ionic bombardment of the oil under the action of the discharge. A similar conclusion was reached by Eichwald[60] as a result of his work with oleic acid in an atmosphere of hydrogen, nitrogen or air. In this case, stearic acid was formed in a 16 per cent yield from oleic acid whether or not hydrogen was present. However, the hydrogen for the reduction, according to Eichwald, was obtained from the oleic acid molecule itself. A more general investigation has been contributed by Petrov and Bogoslovskaya,[61] who subjected straight-run and cracked kerosenes and also certain pure hydrocarbons to voltolization at 7500 volts and 1000 cycle frequency for 6 hours. The yields of polymers from typical olefin, paraffin and aromatic hydrocarbons were 60 per cent, 23-28 per cent and 15 per cent, respectively. Those from aromatics had the highest viscosity but the lowest viscosity index[62] while olefins and paraffins gave polymers of lower viscosity and higher viscosity index. The viscosity of the polymerized materials from olefins and paraffins could be in-

creased by adding naphthene and aromatic hydrocarbons before treatment and the energy expenditure was reduced by such addition.

The effect of varying conditions on the viscosity of the product formed by subjecting cracked kerosene to the action of a silent discharge of 4 to 14 kv. in a Siemen's ozonizer was investigated by Tarasov.[63] The reaction was carried out in an atmosphere of hydrogen and under reduced pressure. Under constant electrical conditions the viscosity increased with the time of application of the discharge, this increase being more rapid after the first 6 hours. The optimum frequency was found to be 500 cycles per second and, at a constant frequency and contact time, the viscosity of the product was raised with increasing electrical power.

For the preparation of lubricating oils by voltolization a wide range of materials, including middle fractions of cracked brown coal tar,[64] hydrogenated and cracked coal tar,[65] alkylated naphthalenes[66] and halogenated paraffins, mixed with aromatics or olefins,[67] have been proposed. Products obtained by subjecting paraffin waxes having molecular weights above 330 (or substances containing substantial amounts of such waxes) to the action of the silent discharge (particularly those of high frequencies) are reported to possess lubricating properties. Addition of these bodies, after removal of hard and soft wax and middle oils, to lubricants is said to furnish oils of lower pour points and increased viscosity indices.[68] Elimination of undesirable substances from the crude products may be effected by vacuum distillation, selective solvent action,[69] fractional precipitation or adsorbent action. Electrical treatment may be carried out, for example, at temperatures of about 80°C. and under reduced pressure with a discharge of about 4000-8000 volts and 50-50,000 cycles, and for a period of time sufficient to raise the viscosity to above 12°Engler at 100°C. Voltolization is favored by the presence of foam-forming agents and also of substances promoting condensation, such as aluminum chloride, boron fluoride and zinc chloride.

Lubricants are obtained by subjecting normally liquid hydrocarbons, poor in hydrogen, to the action of silent discharges and catalytically hydrogenating the resulting products at 150-300°C. and 20-500 atmospheres.[70] Another procedure comprises subjecting an intimate mixture of oil and finely-divided substances, such as brown coal or wood charcoal, to the action of a glow discharge.[71]

The polymers secured by passage of high-tension electric discharges through 10-12 carbon-atom hydrocarbons, alcohols, esters and other organic compounds are said to reduce the pour point of viscous waxy hydrocarbon oils even if added to the extent of less than 5 per cent.[72]

OTHER INDUSTRIAL APPLICATIONS OF THE ACTION OF THE SILENT ELECTRIC DISCHARGE ON HYDROCARBONS

A possible application of the silent electric discharge is in the vapor-phase cracking of petroleum oils for gasoline. According to Rowland[73] the oil vapors are subjected to the action of a high-tension alternating current discharge of frequency not exceeding 10,000 cycles per second. The gasoline thus obtained is stated to need no blending and to be satisfactory as regards antiknock value. In considering the theory of the process, Rowland believes it possible for an electron moving through vapor to carry along with it a molecule of the hydrocarbon. On reaching a hot surface capable of absorbing the electron, the impact may be sufficiently great to cause disruption of the molecule.

The conversion of methane into higher hydrocarbons (e.g., propane) is effected, by Reinecke,[74] by passage of the gas under sub-atmospheric pressure through a reaction tube in which a silent electric discharge is maintained. The time of contact of the gas in the electric field is less than 0.03 second. A modification of this method comprises treating the gas (methane, ethylene, acetylene or their homologues) in a glow discharge followed by a short heating at 900°F.[75]

Several applications of the silent discharge in the purification of hydrocarbon oils have been disclosed. Thus, Bruzac[76] purifies hydrocarbons by submitting them to the action of an electric field so that impurities are electrolyzed and collect at the electrodes. A process for removal of gum-forming constituents from motor benzines has been described[77] in which the benzine is treated with a polymerizing agent, such as sulphuric acid, ferric chloride or aluminum chloride, and then subjected to the action of silent electric discharges under non-oxidizing conditions. Alternatively, treatment with the discharge may be carried out prior to polymerization.

Polymerization of resin- and gum-producing constituents of coal or manufactured gases is effected by compressing the latter to 5 atmospheres (or more) pressure, heating to 150-200°C., and then treating with a silent discharge.[78] Afterwards the gases, at the same temperature and pressure, are washed with an absorbing oil to remove the polymers. In the process of Stanton[79] for dewaxing of petroleum oils, the latter are cooled and diluted with naphtha or other solvents and the solution subjected to the action of a high-tension direct current of 125-250 kv. The oil is pumped into a hollow perforated anode from which it escapes in jets towards a horizontal cathode shell, the latter being slowly rotated. Wax is scraped continuously from the shell and oil withdrawn from the bottom.

Aldehydes are obtained by the action of a high-frequency, high-tension discharge on mixtures of paraffin hydrocarbons and oxygen, an illustration of such being the synthesis of formaldehyde from methane and oxygen.[80] If nitrogen be present also the resulting product is hexamethylenetetramine.[81] Carbon dioxide may be substituted for oxygen, though in this instance the aldehyde formed depends upon the proportion of the reactants. For example, when the concentration of carbon dioxide is equal to or greater than that of methane, formation of formaldehyde takes place.[82] When the hydrocarbon is in excess acetaldehyde is the main product.[83] In the latter instance catalysts, such as alkaline earth oxides or carbonates, may be employed.

The reduction of oxygen-containing compounds by hydrogen (or methane) in a silent discharge is described by Stuart and Try.[84] This procedure is reported applicable for preparing hydrocarbons from the creosote fraction of coal tar.

THE DECOMPOSITION OF HYDROCARBONS BY OTHER FORMS OF ENERGY

Although the photochemical decomposition of hydrocarbons as a class has received little systematic study, that of acetylene has been more carefully investigated and presents features of interest. It was shown by Reinicke[85] that although sunlight, or light from an incandescent lamp or an iron arc, did not produce any change in acetylene, this hydrocarbon (at pressures of 1 to 10 atmospheres) was polymerized to a yellow, amorphous, insoluble solid when illuminated by a quartz mercury arc. The radiation responsible for this action had a shorter wave-length than 3000 Å, since polymerization was stopped when a screen of Uviolglass was interposed between the light source and the reaction tube. By exposure of acetylene in a glass vessel at constant temperature to radiation from a "hot" mercury vapor arc, Lind and Livingston[86] obtained a brown cuprene-like product, reaction apparently taking place in one step with no side reactions or gaseous products. Light of wave lengths greater than about 2500 Å was not effective in causing polymerization and the quantum yield (i.e., ratio of molecules polymerized to light quanta absorbed) was found to be 9.2 ± 1.5. This is about half the yield per ion pair by the action of alpha particles or about equal to the average yield per ion. In this connection, Lind[87] points out that the primary step in both photochemical and ionization reactions (in the latter case such as produced by alpha particles) is probably activation involving a single electron in a single molecule. Formation of a gas ion can occur only by complete removal of an electron from the molecule which photochemical activation is attributed by Lind to a shift of an electron from its normal orbit to one of higher energy. In both ionic and photo-reactions, changes normally requiring high temperatures are induced at room temperature.

In the reactions produced by ionization, clustering appears to be an important step which prevents the development of a chain reaction and also enables the molecules to withstand the shattering effect of ionizing forces. In photochemical changes, clustering around an excited molecule is also assumed by Lind to occur.

Nikoforov and Runtzo[88] observed that chemically pure bivinyl was not affected in the gaseous state by light from a quartz mercury-vapor lamp. On the other hand the technical product (70 per cent bivinyl and the remainder chiefly butene-2) after 80 hours gave a white solid, insoluble in alcohol, ether and benzene. A mercury-sensitized photochemical polymerization of cyclopropane under the influence of the 2536 Å. radiation of mercury was noted by Harris, Ashdown and Armstrong.[89] The product obtained was a viscous, colorless oil having a boiling point of nearly 300°C. at 760 mm. pressure. The structure suggested for this polymer was $(CH_2)_n$.

Polymerization of acetylene, at 0.5-10 mm. pressure and 20-500°C., by excited (electrically) mercury atoms is described by Melville.[90] The mercury atoms apparently form a complex with the hydrocarbon which then adds on more acetylene molecules. The chain length (number of acetylene molecules polymerized per excited mercury atom deactivated by the hydrocarbon) was independent of the pressure, of the rate at which the chains were started, and was not affected by packing the reaction tube. Under the same conditions ethylene polymerized, but the first stage of the reaction seemed to be dissociation into hydrogen and acetylene. Also

the polymers from the latter (with ethylene as the initial material) underwent partial hydrogenation.

The catalytic influence of mercury vapor on the condensation of acetylene in ultraviolet light has been discussed by Kemula[91] and also by Toul.[92] Jungers and Taylor[93] have shown that the mercury-photosensitized polymerization of both acetylene and deuterioacetylene takes place at low pressures at a rate roughly proportional to the pressure. In the range 0.7-4 cm. the rate was found to be independent of the pressure and was 30 per cent greater with acetylene than with deuterioacetylene. It was observed by Livingston and Schiflett[94] that in addition to hard insoluble solid polymers, benzene is also formed from acetylene at 250-400°C. and 1 atmosphere pressure under the influence of light from a quartz-mercury arc. It appears, therefore, that the products of photochemical polymerization of acetylene at high temperatures closely resemble those obtained by thermal polymerization.

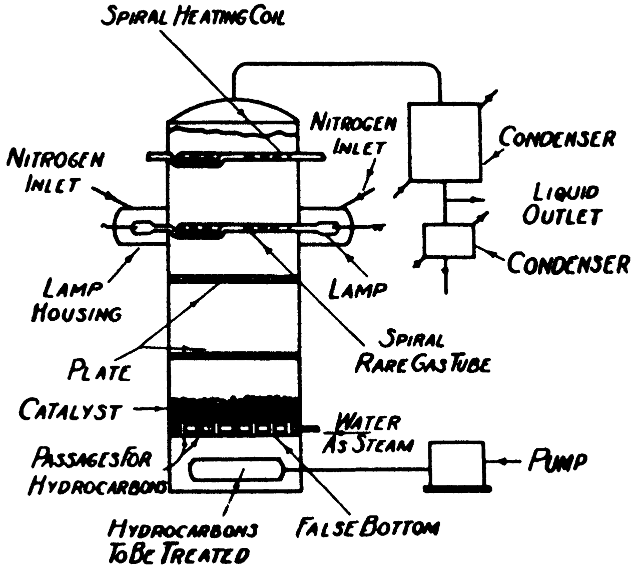

FIG. 87.—Sketch of Apparatus for Treating Hydrocarbons with Rare-Gas-Lamp Radiations. (W. O. Mitscherling)

Under the influence of radiations from a rare-gas lamp, (e.g., one containing argon), hydrocarbons, such as gasoline, are said to be oxidized to alcohols and ketones by perborates and percarbonates.[95] A metal compound, such as copper hydroxide, which increases the electrical conductivity of the hydrocarbon material

undergoing treatment should be present. Radiations, such as those from a positive column neon lamp, are also recommended for this purpose.[96] Fig. 87 shows an apparatus which may be employed in this case.

Under the action of α-particles and β-radiations, hydrocarbons undergo extensive decomposition and polymerization. In the case of acetylene, a solid, insoluble polymer is the main product from the action of alpha particles,[97] cathode rays[98] and high frequency electromagnetic fields.[99] During the polymerization of acetylene under the influence of alpha particles, the velocity of reaction is increased by dilution with gases such as nitrogen, helium, neon, argon, krypton, xenon and carbon dioxide. To explain this increase, it is assumed that an inert gas ion is formed capable of serving as the center of a cluster of molecules and thus promotes polymerization.[100] It is reported that methane at atmospheric pressure photochemically decomposes when irradiated with light which is transmitted through a thin fluorite window from a hydrogen discharge tube. Hydrogen and unsaturated hydrocarbons are found in the resulting products.[101]

The decomposition of hexane, cyclohexane and benzene in the positive-ray tube has been examined by Conrad[102] with the aid of the mass spectrograph. Evidence of the existence of a large number of radicals from C_1 to C_6 was obtained and the conclusion was reached that under the conditions of the discharge a free radical tends to pass into a stable compound by expulsion of a hydrogen atom with formation of a double bond. Both cyclopentane and cyclopentene under the influence of radon have been found to yield liquid products, the ratio of the hydrocarbon molecules decomposed to the number of ions being 1.7 in the case of cyclopentane and 4.5 in the case of cyclopentene.[103]

The synthesis of liquid hydrocarbons from gaseous aliphatics is described by Hillis.[104] The gases are treated with cathode rays and x-rays and the resulting material is conducted into a reaction zone between oppositely charged electrodes where it is mixed with mercury vapor (under heat and pressure) and subjected to an arc discharge in the presence of ultraviolet light. Nickel powder in the reaction zone is reported to facilitate elimination of hydrogen from the simpler molecules and formation of complex molecules with a larger number of carbon atoms.

Henry[105] prepares gasoline of high antiknock value from petroleum hydrocarbon vapors by subjecting the latter to an electromagnetic light and wave field at 24-205°C. The lower boiling fractions from the condensed gasoline are recycled through a second electromagnetic wave field to yield further quantities of liquids. As an alternative procedure, preheated vapors are led through a cracking coil (inductively heated by a high-frequency current) so that the temperature is suddenly increased and cracking takes place simultaneously.[106] The superheated gases are then expanded into a large chamber where they are exposed to the action of a high-frequency oscillating electromagnetic field.

In a process of Plauson,[107] liquid hydrocarbons are produced by subjecting gaseous hydrocarbons or water-gas to an intense beam of β-rays (having a velocity of at least half that of light) or to the joint effect of such β-rays and the x-rays produced from them by secondary action with such substances as quartz or feldspar. Reaction may be facilitated by the use of rotating electromagnetic fields and catalysts of the same types as those employed in the synthesis of hydrocarbons from water gas.[108] The yields of liquid hydrocarbons are reported to be increased by carrying out operations at high pressures and temperatures. If the irradiated gases contain water vapor, the products are said to include ketones and alcohols as well as liquid hydrocarbons. Liquid hydrocarbons of the paraffin and olefin series can also be made from water gas and volatile gases from coal. The treatment of the gas mixture consists in heating to not over 600°C. and subjecting to the action of ultraviolet light, an electrostatic field at about 80,000 to 100,000 volts and a nickel-tin catalyst having a trace of mercury.[109]

Discoloration of hydrocarbon motor fuels (due to exposure to light) is prevented by subjecting the liquids to actinic light and simultaneously treating with water.[110] In place of the latter an aqueous solution of methanol or glycol can be used. The proportion of water present should be about 0.01 per cent of the fuel. Alternatively, 0.05-0.5 per cent of an aliphatic monohydric acid may be added to the hydrocarbons.

Chapter 10

Reaction of Hydrocarbons with Steam, Carbon Dioxide and Ammonia at High Temperatures

General methods for the industrial production of hydrogen include electrolysis of water, the water-gas reaction, steam-iron reaction, pyrolysis and partial oxidation of hydrocarbons, particularly methane, and the decomposition of methane with steam.[1] Of these, the last three are of particular interest to the petroleum industry. Pyrolysis of hydrocarbons to hydrogen and carbon has been previously discussed (see Chapter 7). In this chapter the reaction of steam with, and to some extent partial oxidation of, hydrocarbons is described.

Although hydrocarbons and steam at high temperatures yield principally hydrogen and carbon monoxide (or dioxide), it is of interest to note that in some instances alcohols are formed at atmospheric pressure.[2] The formation of methyl alcohol from methane is believed to take place thus:

$$\begin{aligned} CH_4 + H_2O &\longrightarrow CO + 3H_2 \\ CO + 3H_2 &\longrightarrow CH_3OH + H_2 \end{aligned}$$

A 57 per cent yield is reported. Ethyl alcohol is said to be obtained in a similar manner from certain gas mixtures.

REACTIONS OF HYDROCARBONS WITH STEAM

In the absence of active catalysts little reaction between hydrocarbons and steam takes place except at very high temperatures. In the presence of contact agents, however, hydrogen and the oxides of carbon are produced. In the case of methane the two main reactions may be represented by:

$$CH_4 + H_2O \longrightarrow CO + 3H_2 \qquad (1)$$

$$\text{and} \quad CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2 \qquad (2)$$

Both of these are reversible and take place simultaneously at temperatures above 500°C. The equilibrium constants indicate that both would proceed to completion at about 1000°C.[3] Although this is true for the first reaction (in the presence of catalysts) at such temperatures, in practice the second one is suppressed (except when a very large excess of steam is present) because the carbon dioxide formed reacts with hydrogen to yield carbon monoxide and water according to the well known water-gas equilibrium:

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \qquad (3)$$

In the presence of substances which catalyze the water-gas reaction, the extent to which reactions (1) and (2) proceed will be controlled by the water-gas equilibrium. At about 1000°C. this equilibrium is almost completely in favor of carbon monoxide and steam, while at temperatures of about 400°C. only a small proportion of carbon monoxide is present in the equilibrium mixture.

---

[1] For a discussion of these various methods, see L. Jacque, *Ann. combustibles liquides*, 1934, **9**, 7; *J. Inst. Pet. Tech.*, 1934, **20**, 320A; *Chem. Abs.*, 1934, **28**, 3215; *Revue Ind. minerale*, 1934, **313**, 18; *Chem. Abs.*, 1934, **28**, 4859. The latter method has also been investigated by V. A. Karzhavin (*Chem. Eng. Congr. World Power Conf.*, 1936, C17).

[2] Christesco, *Chaleur & ind.*, 1934, **15** (167), 456; *Chem. Abs.*, 1934, **28**, 6423.

[3] For a discussion of these constants, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

In general, it has been found that methane and steam (at high temperatures) yield almost exclusively hydrogen and carbon monoxide. However, by using a very large excess of steam it has been possible to realize reaction (2) almost exclusively at temperatures as high as 1000°C. The latter reaction also occurs with methane and steam in the presence of catalysts at temperatures of about 500-600°C. Complete decomposition of methane apparently does not take place and high conversions are attained only with a large excess of steam over that theoretically required.

Higher saturated and unsaturated hydrocarbons may also undergo interaction with steam in the presence of catalysts, mainly hydrogen and carbon monoxide being formed at high temperatures. When operating with the homologues of methane, there appears to be a greater tendency for the formation of unstable intermediate products and fouling of the contact agent by carbonaceous deposits.

The reaction of methane with steam and carbon dioxide at temperatures of about 850°C. has been investigated by Padovani.[4] With porous refractory materials impregnated with nickel, equimolecular proportions of methane and steam were almost completely converted into carbon monoxide and hydrogen with a time of contact of about 4 seconds. The methane content of the treated gas was about .3 per cent and only traces of carbon dioxide were present. Cobalt also was satisfactory, and activators which could be incorporated included the oxides of aluminum, thorium, zinc and magnesium. It was reported that in spite of the higher temperature employed, organic sulphur did not reduce the activity of the catalysts. In view of the fact that, in the absence of steam, methane was decomposed into carbon and hydrogen in the presence of the nickel catalyst, Padovani believed that reaction between methane and steam proceeds through decomposition into carbon and hydrogen and subsequent reaction of the carbon with steam.

$$\begin{aligned} CH_4 &\longrightarrow C + 2H_2 \\ C + H_2O &\longrightarrow CO + H_2 \\ C + 2H_2O &\longrightarrow CO_2 + 2H_2 \end{aligned}$$

Fireclay impregnated with 6.4 per cent of reduced nickel was employed by Karzhavin and his collaborators[5] for the conversion of methane-steam mixtures into carbon monoxide and hydrogen at 1000°C. They observed that the activity of this catalyst was increased by the addition of as much as 1 per cent of magnesium oxide. Larger proportions of this material, however, caused a decline in activity. This nickel catalyst retained its effectiveness at 1000°C. even after prolonged use, and loss of metal as volatile nickel carbonyl was negligible. The presence of hydrogen sulphide and organic sulphur compounds (0.03-0.5 per cent) caused a slight initial reduction in catalyst activity, which then remained constant. This contrasts markedly with the rapid inactivation (by sulphur compounds) of nickel employed in the methane-steam reaction at temperatures of 500-600°C.[6] When using gaseous hydrocarbon mixtures, containing methane homologues, some deposition of soot takes place, this increasing with the proportion of hydrocarbons higher than methane in the hydrocarbon mixture. However, natural gas containing 87.4 per cent of methane has been successfully reacted with steam in a semi-commercial apparatus by Karzhavin, Elektronov and Ovchinnikov,[7] using a catalyst of nickel supported on a porous grog and at a temperature of about 1350°C. Under these conditions, a mixture of 1 volume of natural gas and 1.9 volumes of steam produced 3.3 volumes of a mixture containing 9 per cent carbon dioxide, 22 per cent carbon monoxide, 64 per cent hydrogen, 0.8 per cent methane and 4.2 per cent nitrogen. Fig. 88 shows the reaction chamber employed. In the actual operation the gas-steam mixture enters at the lower part of the apparatus, passes upward and is heated by the hot regenerative packing and catalyst. The converted gas leaves at the upper part of the chamber. When the packing has cooled so that the temperature at the top of the chamber is about 1280°C., the conversion process is interrupted. The chamber is then reheated by the combustion of natural gas with air, both entering at the top, and the combustion products leave at the bottom of the chamber. The conversion cycle is then repeated, each one lasting about 10 minutes.

On the other hand, substitution of ethylene for methane results in troublesome carbon deposition.[8] Experiments with mixtures of this olefin and steam have shown that even when equilibrium is attained in an equimolecular mixture enough ethylene remains in the gas to furnish carbon by thermal decomposition. This latter reaction begins about 700°C. but can be suppressed by an excess of steam. Complete conversion of a gas containing 30 per cent of olefins and 50 per cent of methane may be obtained by preheating it to 650°C., and adding steam and 30-60 per cent of oxygen and conducting the reactants over a nickel catalyst. In this way the temperature is quickly raised to 1000-1100°C. and carbon formation is prevented.

According to Candea and Kühn,[9] natural gas containing 96.4 per cent of methane was almost completely transformed by reaction with 3 volumes of steam at 1000°C. in the presence of a catalyst containing iron, nickel and manganese, and with a time of contact of 20 seconds. The gaseous products contained 70 per cent of hydrogen and 20 per cent of carbon monoxide. Under similar conditions kerosene yielded 30 per cent hydrogen and 70 per cent carbon monoxide. Decomposition of a heavy residuum oil (with steam) at 800-900°C. furnished a good illuminating gas which could be employed also as a fuel for gas engines. Another use for such gases, after removal of water vapor, is in the brazing of iron or steel at 1100°C.[10]

It has been found by Schmidt[11] that coke from brown coal is effective for the conversion of methane and its homologues into carbon monoxide and hydrogen mixtures by reaction with steam at 950-1025°C. The gaseous products (containing 70 per cent of hydrogen) may be transformed into carbon dioxide and more hydrogen by further reaction with steam at 500°C. in the presence of the same agent.

From the point of view of hydrogen production from methane, the reaction

$$CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2$$

would appear most attractive since it yields more hydrogen than the competing reaction,

$$CH_4 + H_2O \longrightarrow CO + 3H_2$$

and also should furnish a gas mixture from which the carbon dioxide can be readily eliminated. However, for reasons already discussed, it has been found difficult to carry the former reaction to completion except in the presence of a very large excess of steam. Consequently the same overall effect has usually been attained by a two-stage process, in which high temperatures and steam are employed to decompose the hydrocarbon into hydrogen and carbon monoxide, the latter constituent being further reacted with steam at a lower temperature (in the second stage) to give carbon dioxide and hydrogen. It has been pointed out by Karzhavin[12] that complete transformation of methane (in the presence of nickel) is only possible at 500-600°C. if excess steam is employed and the carbon dioxide formed is absorbed by calcium oxide incorporated in the catalyst mass. However, regeneration of calcium carbonate at 850-900°C. destroys the activity of the catalyst. If ignited dolomite is substituted for lime, not only is carbon dioxide absorbed but any carbon monoxide present is said to be converted into carbon dioxide by the steam. According to Takenaka,[13] an active agent for accelerating the reaction,

$$CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2$$

at low temperatures (650°C.) consisted of a mixture of potassium carbonate, alumina and reduced nickel.

Transformation of methane, and other hydrocarbons, by steam into mixtures of hydrogen and carbon dioxide, with very little carbon monoxide, has been realized experimentally by Matignon and Seon[14] by the use of certain catalysts at temperatures above 1000°C. The best of these was zirconia while thoria ranked next and ferric oxide, alumina, ferric oxide plus 10 per cent potassium carbonate, and zirconized asbestos were less active. Passage of a gas consisting of 63.7 per cent methane, 14.4 per cent nitrogen, 10.0 per cent hydrogen, 7.3 per cent carbon monoxide, 3.8 per cent oxygen and traces of ethylene with an excess of steam over zirconia at about 1000°C. (with a time of contact of 7 seconds) furnished a product containing 74 per cent hydrogen, 17 per cent carbon dioxide and no carbon monoxide. The steam proportion was varied up to 80 times the theoretical quantity but it was found that the best results were obtained by keeping the excess small. Matignon and Seon also[14] studied the conversion of hexane, benzene, *m*-xylene, cyclohexane, cyclohexene, gas oil and fuel oil into carbon dioxide and hydrogen by reaction with steam in the presence of the zirconia catalyst at about 1000°C. At a contact time of 3 seconds, the hydrogen content of the gas from hexane was 78.5 per cent while no carbon was deposited and the carbon monoxide was very low.

$$C_6H_{14} + 12H_2O \longrightarrow 6CO_2 + 19H_2$$

Benzene, freed from thiophene, yielded gas containing 53 per cent of hydrogen at 1050°C. and one second contact time and a gas containing 56 per cent hydrogen at 1075°C. and 1.1 seconds contact time. At 1000°C. *m*-xylene, with twice the theoretical quantity of steam, gave a reaction product containing 64 per cent of hydrogen and those from cyclohexane and cyclohexene contained 48.5 per cent and 58.2 per cent of hydrogen, respectively. In the presence of zirconia at 1000-1050°C. reaction of steam with gas oil and mazout[15] yielded 76.2 per cent and 67.9 per cent of hydrogen, respectively. In the case of these higher hydrocarbons and steam, methane and ethylene were always observed as intermediate products but disappeared with increased contact time.

Treatment of benzene with deuterium oxide (heavy water) at 200°C., using nickel on kieselguhr as a catalyst, results in replacement of the hydrogen in the aromatic hydrocarbon by deuterium.[16] Removal of water, after each operation, and addition of fresh portions of deuterium oxide yields, successively, compounds varying in composition from C_6H_5D to C_6D_6.[17]

The equilibrium constants of the reaction,

$$CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2$$

at temperatures between 400-490°C. have been determined by Ghosh, Chakravarty and Bakshi,[18] using a catalyst containing nickel, thoria and ceria.

Reaction between Methane and Carbon Dioxide

In the presence of contact agents of the same type as those employed in the methane-steam reactions, methane interacts with carbon dioxide according to the reversible equation:

$$CH_4 + CO_2 \rightleftharpoons 2H_2 + 2CO - 61 \text{ kg. cal.}$$

This is essentially the sum of the two reactions,

$$CH_4 \longrightarrow C + 2H_2 \qquad \text{and} \qquad C + CO_2 \longrightarrow 2CO$$

[17] The preparation of C_6D_6 by other methods is described by H. Erlenmeyer and H. Lobeck (*Helv. Chim. Acta*, 1935, **18**, 1464; *Chem. Abs.*, 1936, **30**, 1751; *Brit. Chem. Abs.* **A** 1936 61) and N. Morita and T. Titani (*Bull. Chem. Soc. Japan*, 1935, **10**, 557; *Chem. Abs.*, 1936, **30**, 1751; *Brit. Chem. Abs.* **A**, 1936, 195). The latter investigators also prepared monodeuteriobenzene.

[18] J. C. Ghosh, K. M. Chakravarty and J. B. Bakshi, *Z. anorg. allgem. Chem.*, 1934, **217**, 277; *Brit. Chem. Abs.* **A**, 1934, 488; *Chem. Abs.*, 1934, **28**, 6613.

and it is possible that the latter effectively represent the actual mechanism of the methane-carbon dioxide reaction. The known equilibrium constant of the decomposition of methane into its elements and the carbon-carbon dioxide reaction may be combined to show the influence of temperature on the methane-carbon dioxide equilibrium. This method of calculation has been employed by Gluud, Klempt and Brodkorb,[19] whose figures for the equilibrium concentration of reactants (calculated as volume per cent of the gaseous mixture) at atmospheric pressure and at various temperatures are shown[20] in Table 56.

TABLE 56.—*Reaction* $CH_4 + CO_2 \rightleftharpoons 2H_2 + 2CO$

	Per Cent			
Temp. °C.	CH_4	CO_2	CO	H_2
450	43.5	43.5	6.5	6.5
550	28.7	28.7	21.3	21.3
650	15.5	15.5	34.5	34.5
750	3.0	3.0	47.0	47.0
850	0.8	0.8	49.2	49.2
900	0.1	0.1	49.9	49.9

It will be seen that complete decomposition of methane by carbon dioxide can only be attained at temperatures of the order of 1000°C. It has been found that catalysts for the methane-steam reaction are also effective for that between methane and carbon dioxide. Padovani and Franchetti[21] have investigated this latter reaction at temperatures of about 850°C. using porous refractory material impregnated with reduced nickel and promoters such as alumina. In a typical experiment, an equimolecular mixture of these latter two gases was passed at atmospheric pressure and a temperature of 850°C. over the catalyst impregnated with 12.5 per cent of nickel and 25.5 per cent of alumina at such a rate that the time of contact of the gases was 9.8 seconds. The gas produced contained 50.9 per cent hydrogen, 47.6 per cent carbon monoxide, 1.1 per cent carbon dioxide and 0.7 per cent methane. Nickel containing small proportions of copper was also found to be very active.

INDUSTRIAL APPLICATIONS OF THE REACTIONS OF HYDROCARBONS WITH STEAM AND CARBON DIOXIDE

The production of hydrogen from gaseous hydrocarbons is carried out industrially in a two-stage process, in which the hydrocarbons are first reacted with steam, or carbon dioxide, at high temperatures to furnish a mixture of hydrogen and carbon monoxide and the latter substance subsequently converted (in the second stage) into hydrogen and carbon dioxide by reaction with a further quantity of steam and at a lower temperature. Both stages may be effected in the presence of metallic catalysts though refractory materials of large surface and high heat content may be employed in the high temperature zone.

The chief technical difficulty confronting large scale operation is the necessity of supplying large amounts of heat to the reacting gases (owing to the high endothermicity of the reaction) at a high temperature level. In some instances this has been overcome by employing externally fired reaction chambers in conjunction with regenerative heat-exchangers of special design.[22] Wietzel and Hennicke[23] propose reaction chambers composed of highly alloyed steels, such as those containing chromium and nickel. These reactors, which are externally heated to about 600-1000°C., are constructed so that their length is very large in proportion to their cross-sectional area. For example, in one method[24] these chambers are pipes passing vertically through the roof and floor of a furnace and are arranged in rows along the sides. The burner is centered at the top and the exhaust gases are removed through openings in a horizontal flue on the bottom of the furnace. Instead of using externally heated units, the reaction between hydrocarbons and steam may be combined with some exothermic process, such as the incomplete combustion of hydrocarbons with air or oxygen. Alternatively, the operations can be carried out intermittently in the presence of heat-storing materials, which are periodically heated by direct firing. In this case the steam reaction and the firing cycle are effected in alternation exactly as in the well-known process for the manufacture of water gas.

FIG. 89.—General View of Plant for Producing Hydrogen from Hydrocarbons.

In a process described by Odell,[25] a mixture of steam and propane or butane is introduced into a highly heated fuel bed to produce a gas containing essentially hydrogen and carbon monoxide in the ratio of 2-3 to 1. It is also proposed to carry out the steam-hydrocarbon reaction by mixing the latter material with a stream of superheated steam, preheating the mixture to above 540°C. and passing it downwards, through an incandescent fuel bed (previously heated in a separate firing cycle by an air blast). The resulting product contains 2-3.5 times as much hydrogen as carbon monoxide, and is said to be free from suspended carbon resulting from the pyrolysis of the hydrocarbon material.[26]

According to Namikawa,[27] the decomposition of hydrocarbons by steam is effected over a nickel catalyst in a reaction tube placed in the center of a water-gas generator. The gaseous products then pass through hot coke surrounding the catalyst tube thus giving a mixture containing 25-34 per cent of carbon monoxide and 57-59 per cent of hydrogen. Odell[28] suggests treatment of gaseous or atomized hydrocarbons with steam in the presence of the hot coke obtained by the carbonization of solid fuels, e.g., in vertical retorts.

In another procedure, air is passed through a regenerator chamber and used to burn a combustible gas in a checker-filled, or other, reaction conduit, the waste gases serving to heat a boiler.[29] Natural gas and steam, together with carbon dioxide if higher ratios of carbon monoxide to hydrogen are desired, are then passed through the reaction chamber and regenerator in a reverse direction to the fuel gas, and the cycle of operations is repeated.

Mixtures of hydrogen and carbon monoxide were produced by Russell and Hanks[30] by reaction of methane and steam at temperatures above 760°C. in a tower packed with a catalyst. The latter consisted of alumina, or rare-earth oxide, impregnated with finely-divided nickel or cobalt. Heating was accomplished by surface combustion of gas-air mixtures on porous fireclay in a vertical tube extending the whole length of the longitudinal axis of the tower. The gases resulting from this process were then passed with more steam over a ferric oxide catalyst below 550°C. to yield carbon dioxide and hydrogen. The former was removed by appropriate scrubbers.

A combustible gas has been obtained by Odell[31] by the reaction of gaseous hydrocarbons and steam. He describes an apparatus in which the gaseous mixture is passed along refractory bricks at incandescent heat. The resulting gas, rich in hydrogen, is then admixed with a gas containing nitrogen oxides. Part of the hydrogen reduces the nitrogen oxides to nitrogen and water. This results in a nitrogen oxide-free gas, useful where a non-corrosive gas is required.

In a number of processes, part of the heat required for the endothermic reaction is supplied by admixture of oxygen (usually in the form of air) with the reactants, whereby partial combustion of the hydrocarbon (e.g., methane) is

$$CH_4 + \tfrac{1}{2}O_2 \longrightarrow CO + 2H_2 + 8 \text{ kg. cal.}$$

effected. When air is used as a source of oxygen, the resulting gas mixture will, of course, contain nitrogen. It has been shown by Padovani and Franchetti[32] that the partial combustion of methane, or gases containing methane, with air or oxygen takes place smoothly and completely in the presence of nickel catalysts at temperatures of 850-1200°C. Only small amounts of undecomposed methane remain and practically no carbon dioxide is formed. Voorhees[33] suggests the application of pressures as high as 300 atmospheres, the resulting carbon monoxide being subsequently converted into carbon dioxide and hydrogen by catalytic reaction with steam at the same pressure.

Klempt[34] subjected hydrocarbons to reaction with steam in the presence of catalysts so as to be only partially converted into carbon monoxide and hydrogen. The resulting mixture was then further oxidized with air whereby the remaining hydrocarbon material was transformed chiefly into carbon monoxide and hydrogen. Carbon monoxide was changed by preferential oxidation into carbon dioxide and absorption of the latter left a mixture of hydrogen and nitrogen suitable for the ammonia synthesis.

In a process of Wilcox,[35] hydrocarbon gases together with the requisite proportions of steam and air are passed through a conduit preheated to above 1150°C. by combustion of fuel gas therein. The hot gases, consisting of a mixture of hydrogen, nitrogen and oxides of carbon, are conducted through a regenerator, and sufficient steam then added to lower their temperature to about 500°C. After this they are led successively through an iron oxide catalyst and sufficient lime to remove part of the carbon dioxide formed. More steam is added, causing their temperature to fall to about 370°C., and the gases again passed over an iron oxide catalyst and finally freed from carbon dioxide.

Wilcox[36] also prepared mixtures of hydrogen and nitrogen by reacting methane with steam at temperatures above 980°C. and mixing the resulting hot gas with preheated air so that partial combustion took place. The gases were cooled by heat exchange with ingoing materials and the carbon dioxide present then eliminated. Another procedure comprises passage of a mixture of hydrocarbon gas and steam through a conduit filled with permeable refractory material previously heated to above 1090°C. by an air-gas blast.[37] Simultaneously with the steam reaction (in which the gas direction is countercurrent to the direction of the combustion gases during the heating cycle) a controlled volume of air, preheated to above 980°C., is introduced at an intermediate point in the reaction zone. The temperature is raised by the ensuing partial combustion and by adjusting the volume of air, hydrogen-nitrogen mixtures of predetermined composition can be obtained. Wilcox[38] has also developed a process in which the requisite amount of oxygen is added to the hot products of the methane-steam reaction after the latter has proceeded only 80 per cent towards completion. The steam reaction is carried out in reactors externally heated to above 980°C. and the oxygen addition is so regulated that all the residual methane is converted into carbon monoxide and all hydrogen in excess of twice the volume of carbon monoxide is oxidized to steam. The resulting mixture can be utilized for methanol synthesis. A closed heat-recovery system for use in the interaction of methane with a large excess of steam (0.8-1.9 lb. per cu. ft. of dry gas) has been described by Svanoe.[39]

In addition to possessing high activity, the catalyst employed for the production of hydrogen and carbon monoxide from hydrocarbons and steam (or carbon dioxide) must be physically stable at high temperatures and resistant to poisoning by substances such as hydrogen sulphide.[40] A number of these have been described. For example, a paste consisting of a mixture of the hydroxides or carbonates of iron, nickel or cobalt and chromium or aluminum hydroxide is heated to remove uncombined water and then further dried at 870-1040°C. for 12 hours to 3 days.[41] During this latter period the mass is continuously treated with a current of gas free from catalyst poisons. Another procedure comprises impregnating alundum cement with nickel or cobalt nitrates, igniting the mass and then reducing the oxide with hydrogen to the metallic condition.[42] The resulting powder is mixed with black nickel oxide, the mixture pressed into cubes and the latter sintered in hydrogen at 1000°C. Woodhouse[43] recommends nickel and cerium nitrates supported on pumice and reduced in hydrogen. A catalyst was prepared by Davis and Franceway[44] by incorporating phosphoric acid with an oxide of nickel or chromium and a refractory oxide such as alumina, thoria or zirconia, and baking the mixture at a temperature below the temperature of fusion of either oxide.

The conversion of liquid, semi-solid and solid hydrocarbons into noncondensable gases without deposition of carbon was effected by Banc[45] by mixing them with superheated steam and passing the mixture through a contact mass maintained at 700-1000°C. According to Brassert,[46] simultaneous passage of natural gas and low-grade gases containing carbon dioxide through a highly heated zone results in cracking of the hydrocarbons to hydrogen and carbon and reaction of the latter with carbon dioxide to give carbon monoxide.

The low temperature reaction between methane and steam (usually in considerable excess) for the production of mixtures of hydrogen and carbon dioxide has attracted attention since the latter may be eliminated by relatively simple means. In practice, however, complete decomposition of the hydrocarbon in one treatment can only be achieved by the use of a very large excess of steam. Also the reaction is strongly endothermic. For these reasons it has been found convenient generally to attain the same results in a two-stage process, as previously described.

Harter[47] proposes to convert methane, or gases rich in methane, into hydrogen and carbon dioxide by reaction with steam at 550-600°C. Catalysts such as active carbon and the oxides of iron, nickel, cobalt and copper, admixed with difficultly reducible metallic oxides, may be employed. Reactivation of the catalyst is effected by subjecting it to a gas containing hydrogen and carbon monoxide (produced by partial combustion of methane) followed by a short treatment with steam, with or without air. Another contact agent is prepared by adding a solution of potassium carbonate to an aqueous solution containing the nitrates of nickel, aluminum and magnesium, mixing the precipitate with potassium nitrate and reducing the dried mixture in a current of hydrogen.[48] Passage of 1 volume of methane and 6.2 volumes of steam over this catalyst at 450-650°C. yields a gas containing carbon dioxide and hydrogen in the proportions of 1 :4.

---

[40] Removal of sulphur compounds from gaseous hydrocarbons before submitting the latter to treatment with steam is described by G. Wietzel, W. Haller and W. Hennicke, German P. 578,824, 1933, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, **28**, 866.

According to Porter's method,[49] only small amounts of carbon monoxide occur with the carbon dioxide and hydrogen produced. One of his catalysts may be obtained by adding an aqueous nickel and aluminum salt solution to an excess of aqueous alkali (so that the solution may be basic during precipitation), supporting the resulting mixed precipitate on magnesium oxide or magnesium fluoride and drying. In this case, the aluminum acts as a promoter for the nickel catalyst. This investigator also advocates the use of chromium or molybdenum oxides, substantially free of nickel, iron or cobalt.[49a] Another contact agent which may be employed consists of palladium admixed with the oxides of two of the following metals, magnesium, beryllium, cerium, titanium, chromium, thorium or tungsten.[49b]

Woodhouse[50] decomposed methane with steam in the presence of catalysts at a temperature of 550°C., followed by further reaction with steam, and carbon dioxide-absorption at 250-450°C. A contact agent for this low-temperature operation was made by treating a nickel salt solution with a precipitant such as calcium hydroxide.[51] The precipitate was calcined, and then reduced in an atmosphere of hydrogen. Cobalt compounds may also be used. Heat for the reaction between hydrocarbons and steam is supplied, in the process of Beekley,[52] by continuously burning fuel gas in heat-exchange relation to, but out of direct contact with, the reactants. Residual heat is afterwards removed from the combustion products by heat exchange with water from which steam for the reaction is generated.

Another modification is described by Larson[53] in which, after partial conversion of the methane-steam mixture has taken place, the temperature of the reacting gases is raised by the introduction of oxygen. The resulting partial combustion produces sufficient heat to render the hydrocarbon-steam reaction practically thermally self-supporting and heat is supplied to the inlet gases by heat exchange with the hot gaseous products.

In the process of Spalding,[54] natural gas is saturated with water vapor at 83°C. and then passed over a catalyst at 390°C. to produce carbon monoxide and hydrogen. The resulting mixture is saturated with steam and conducted through a second catalyst chamber at 330-340°C. to convert the carbon monoxide and steam into carbon dioxide and hydrogen. The hot gases are compressed to 1.5-2 atmospheres and forced through a tower down which flows the effluent water from the first two operations. In this manner the water is heated to about 120°C. before being returned to the system.

The production of hydrogen from methane was effected by Williams[55] by the use of the steam reaction at temperatures of 300-500°C. and at superatmospheric pressures. A nickel catalyst containing a large proportion of an alkaline earth oxide, such as lime, was used. As soon as oxides of carbon appeared in the reaction products, the catalyst was regenerated by heating.

"REFORMING" HYDROCARBONS BY PARTIAL REACTION WITH STEAM

An important application of the reaction between hydrocarbons and steam is the so-called reforming of natural and refinery gases. The products of reforming consist of unchanged hydrocarbons as well as hydrogen and oxides of carbon and their composition may be varied by controlling the extent of reaction with steam so as to produce gaseous fuels of almost any desired calorific value from 280 to 1800 B.t.u. per cu. ft. In the Davis reforming process,[56] butane and other hydrocarbon gases of high thermal value are degraded in the presence of a catalyst of metallic nickel in a cycle of operations which includes blasting, reforming and steaming periods in which the generator is heated, cracking of the rich gases and the purging of the machine. The reactor consists of an insulated refractory-lined chamber similar to a water-gas generator and is packed with 1″ x 3″ helical coils of No. 10 gauge nickel wire. Tar and condensable oils are not formed and the activity of the nickel increases with use. Catalyst losses are said to amount to only about 2 cents per 1000 cu. ft. of gas.

Another method of reforming natural or refinery gas, developed by Perry,[57] does not involve the use of catalysts. Instead, the hydrocarbon gas is passed through an incandescent fuel bed, producing a reformed gas, a stiff pitch and deposition of carbon in the fuel bed. The fuel bed is then air-blasted to provide heat to crack more gas, after which the remaining excess carbon is converted into water-gas by steaming. The mixture of reformed and water gases has a calorific value of about 460 B.t.u. per cu. ft., and may be enriched by vaporization of liquid hydrocarbons (e.g., gas oil) with heat from the air blast gases. According to Perry,[58] 1000 cu. ft. of refinery gas of 1600 B.t.u. yields 2000 cu. ft. of 560 B.t.u. gas together with 33 lbs. of coke from which an additional 1000 cu. ft. of blue water-gas can be produced. Overall conversion costs are somewhat less than those for carburetted water-gas. The production of 945 B.t.u. gas by reforming a light distillate of 32 Bé. in a standard 3-shell water-gas machine has been described by Willien.[59]

According to Frey, Huppke and Guyer,[60] a clean fuel gas from hydrocarbons such as propane and butane is obtained by the following procedure: A mixture of steam and hydrocarbons is passed through a series of externally-heated catalyst masses, the gas mixture being preheated between the various stages and hydrocarbon material added at intervals. The catalyst may consist of screens of nickel promoted with alumina. The calorific value of the resultant gas, consisting of mixed gaseous hydrocarbons and water-gas, can be controlled at will.

PRODUCTION OF HYDROCYANIC ACID FROM HYDROCARBONS BY HIGH TEMPERATURE REACTIONS

It has long been known that hydrocyanic acid may be produced by the interaction of hydrocarbons, such as methane, with ammonia at high temperatures and several processes for the manufacture of that material have been developed commercially. It has been shown by Andrussow[61] that good yields of hydrocyanic acid are obtained by passage over platinum gauze at about 1000°C. of a mixture of ammonia, methane and oxygen (or the corresponding amount of air) in proportions corresponding to the equation:—

$$2NH_3 + 3O_2 \text{ (or 14.4 air)} + 2CH_4 \longrightarrow 2HCN + 6H_2O + 230 \text{ kg. cal.}$$

With these proportions of reactants at 1000°C., 58-63 per cent of the ammonia is converted into hydrocyanic acid, about 8-12 per cent to nitrogen and about 26-30 per cent remains undecomposed. The methane is partly transformed into hydrocyanic acid and partly into a mixture of hydrogen and carbon monoxide. A small excess of either ammonia or methane is not harmful but with increasing amounts of methane most of the oxygen is consumed in the formation of carbon monoxide and hydrogen, thus decreasing the yields of hydrocyanic acid. A decreased yield of this acid is also obtained on addition of carbon monoxide to the reaction mixture. Oxidation of ammonia to nitric oxide and, in the presence of methane and other hydrocarbons, to hydrocyanic acid is considered by Andrussow to be a distinct catalytic process taking place in the immediate proximity of the catalyst surface with such rapidity that the intermediate steps can only be followed under very special experimental conditions. In some instances nitric oxide may be substituted for ammonia.[62] A 97 per cent platinum-3 per cent indium alloy gauze also has been suggested for this reaction under about the same conditions.[63]

Another method for preparing hydrogen cyanide comprises conducting ammonia (1 vol.), methane (2-5 vol.) and oxygen (3 vol.) through a silica tube heated to 1300°C.[64] Wood charcoal may be employed as a contact agent.[65] Mixtures of methane and ammonia have been reported to be transformed to hydrogen cyanide in recuperation furnaces under reduced pressure.[66] When temperatures of 500°C. or higher are necessary, it is suggested that the apparatus be made of or lined with aluminum oxide free from silicates.[66a]

Condensation of unsaturated hydrocarbons with ammonia, or substituted ammonias, is known to yield amines under certain conditions, particularly in the presence of catalysts and at relatively low temperatures.[67] However, Egloff and Schaad[68] report the production of amines by the direct combination of noncondensable hydrocarbon gases (from cracking operations) with ammonia at about 650°C. and under pressures ranging from 1000 lbs. per sq. in. to subatmospheric pressures.

Chapter 11

Direct Hydration of Olefins to Alcohols

The direct addition of water to olefin hydrocarbons according to the general equation

$$C_nH_{2n} + H_2O \longrightarrow C_nH_{2n+1}OH$$

would appear to offer possibilities for the commercial synthesis of alcohols. The simplicity of the reaction, as compared with the well-established although indirect methods involving absorption in sulphuric acid, has attracted a large number of investigators.[1] Consideration of the thermodynamics involved has shown that hydration is favored by low temperatures and high pressures. Consequently good yields, which are essential to the industrial success of the process, can be attained only in the presence of catalysts capable of effecting rapid combination at relatively low temperatures.[2]

ETHYLENE

Investigations on the hydration of this olefin have been devoted for the most part to the discovery of contact agents which can fulfill the conditions mentioned above. Several types have been employed and for purposes of classification they may be listed as:

1. Organic catalysts, such as pyridine or quinoline.
2. Inorganic catalysts.
    a. Solutions of acids, e.g., sulphuric or phosphoric.
    b. Acidic salts, as for example, acid phosphates.
    c. Oxide catalysts, as alumina or clays.

Aqueous solutions of nitrogen bases (pyridine or quinoline) or their salts were proposed by Bent and Wik.[3] These are reported applicable to the hydration of ethylene or propene at temperatures below 350°C. and pressures of about 3,000 lbs. per sq. in.

Dilute Mineral Acids as Catalysts. The use of dilute mineral acids has been suggested by many investigators. Dreyfus[4] recommended sulphuric acid of 2 to 10 per cent concentration when operations are carried out under pressure at 150° to 300°C. Higher concentrations, 15 to 60 per cent, of either sulphuric or phosphoric acid are advocated by Metzger.[5] The contact agents may be absorbed on an inert carrier, such as pumice or silica gel, and many contain dissolved silver or lithium sulphate. According to Balcar,[6] any catalyst which is lost during hydration of the olefin may be replaced by the gradual addition of ethyl sulphate. Complete separation of alcohol from ethylene may be accomplished by scrubbing under pressure with water.[7]

---

[1] See, Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[2] The economic aspect of the synthesis of alcohols has been discussed by N. Parrarano (*Giorn. Chim. Appl.*, 1934, **16**, 425; *Brit. Chem. Abs.* **B**, 1934, 1093; *Chem. Abs.*, 1934, **28**, 5803). The equilibria involved in the hydration of olefins are of interest because their study should contribute materially to knowledge of the energy relationships of the olefin hydrocarbons.

Abs.*, 1934, **28**, 5474, 5475; *Brit. Chem. Abs.* **B**, 1934, 492, 568; *J. Inst. Pet. Tech.*, 1934, **20**, 378A. An apparatus

One continuous process comprises contacting the olefin, under a pressure of about 100 atmospheres, with a countercurrent stream of dilute (1 to 10 per cent) aqueous sulphuric acid.[8] The temperature should not exceed 350°C. and the pressure should be sufficiently great to prevent substantial evaporation of the alcohol formed. Concentration of the acid liquor is suppressed by the continual addition of water vapor. After withdrawal of the dilute acid from the reaction zone, it is subjected to distillation (to recover alcohol) and then recirculated.

The formation of ethers during hydration of olefins has been observed by many investigators. Shiffler and Holm[9] noted that the development of such oxygen-containing compounds could be controlled by operating at 120° to 150°C. and 15 to 100 pounds pressure, using 20 to 80 per cent sulphuric acid as the contact agent. Furthermore, after separation of alcohol and ether, recycling of the latter is said to aid in the inhibition of its production.

As previously mentioned, the sulphates of silver or lithium may be employed as promoters. Other metallic sulphates which may be used similarly include those of beryllium, magnesium, zinc, cadmium, aluminum, manganese, chromium, cobalt or nickel.[10] It has been suggested also that the reaction vessel be lined with a metal (such as copper or a copper alloy) which has an electrochemical potential, compared with hydrogen, between +0.2 and −0.4 volts.[11]

Gilliland, Gunness and Bowles[12] used dilute aqueous sulphuric acid (about 3 mole per cent) in determining the equilibrium constants for the hydration of ethylene at 176-307°C. under pressures ranging from 80 to 260 atmospheres. They found that the values for free energy and the equilibrium constant at 200 atmospheres pressure differed by about 10 per cent when calculated from the partial pressures of the reactants and from their fugacities.[13] The explanation offered was that ethylene behaves almost as a perfect gas while deviations of ethanol and steam from the ideal gas laws tend to compensate one another. Polymerization of ethylene was a side reaction above 250°C. and 200 atmospheres pressure, and ether formation at temperatures below 220°C. These investigators found that the following equation expressed the relation between free energy change and temperature in the range studied:

$$\Delta F^\circ = -7780 + 26.2T$$

---

for carrying out hydration under 100 to 1,000 pounds pressure is described by F. J. Metzger, U. S. P. 2,021,564, Nov. 19, 1935, to Air Reduction Co.; *Chem. Abs.*, 1936, **30**, 485. [13] Fugacity is a corrected vapor pressure. For a discussion of such, see Chapter 54.

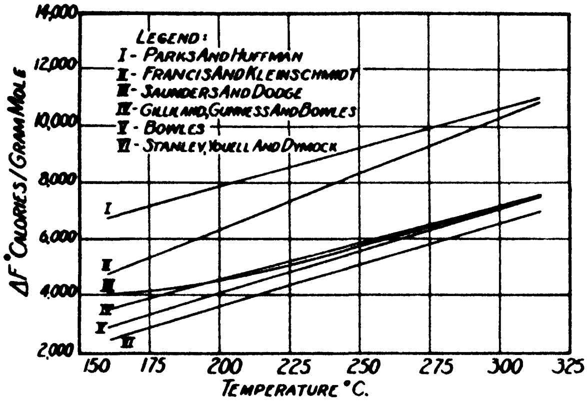
Bowles[14] conducted a series of liquid-phase hydration experiments at 225° to 325°C. and at pressures of about 400 atmospheres. He recommended the equation

$$\Delta F^\circ = -10{,}120 + 30.2T$$

as representing his results.

The expressions deduced by several investigators are compared graphically in Fig. 90, which shows the different relationships for the variation of free energy change with temperature. The experimental data of Sanders and Dodge,[15] of Bowles,[16] of Stanley, Youell and Dymock[17] and of Gilliland, Gunness and Bowles[18] are in good agreement, whereas the computed values of Parks and Huffman[19] and of Francis and Kleinschmidt[20] are much higher. In an attempt to correlate all available experimental data on vapor-phase hydration of ethylene, Gilliland and his collaborators suggest the following:



Courtesy Industrial and Engineering Chemistry

FIG. 90.—Comparison of Results of Various Investigators on Relationship of Temperature and Free Energy of Vapor-phase Hydration of Ethylene. (E. R. Gilliland, R. C. Gunness and V. O. Bowles)

$$\Delta F^\circ = 26.9T - 8300$$

Acidic Salts as Catalysts. Some of the more important members of this group are the acid phosphates of which a large number have been described. Joshua, Stanley and Dymock have suggested the acid orthophosphates of uranium, boron,[21] ferrous iron,[22] cobalt,[23] copper,[24] and manganese.[25] These contact agents may be employed as granules, supported on an inert carrier or in solution for operations effected at temperatures between 100° and 300°C. and at pressures below 250 atmospheres. One method of preparation comprises dissolving the metallic oxide in an aqueous solution of phosphoric acid, the latter being slightly in excess, and evaporating to dryness. The residue is then baked and subsequently formed into tablets or pellets. The mechanical stability of these particles may be improved by incorporation of various binding agents including drying oils such as tung or linseed oil,[26] non-drying vegetable oils (e.g., rape or castor), animal oils and high-molecular weight aliphatic alcohols, acids, ketones, ethers or anhydrides.[27] Many water-soluble substances, as for example, glycerol, mannitol, pectin, gelatin, starch and sucrose, have been suggested also as stabilizing agents.[28]

In addition to the phosphates previously mentioned, Joshua, Stanley and Dymock[29] have proposed also catalysts composed of complex boro-phosphates of copper, iron, or nickel, as well as those of calcium, strontium, barium or magnesium.[30] Some of the results obtained with these contact agents are summarized in Table 57.

on the yield of ethanol. Their experiments were carried out at 20 atmospheres pressure and 275° to 290°C., and about 400 liters (under standard conditions) of ethylene per hour were conducted over the contact agent. The results are shown in Table 58.

TABLE 58.—*Effect of Ethylene-Steam Ratio on Yield of Ethanol with a Manganese Boro-Phosphate Catalyst.*

Molar ratio C_2H_4:H_2O	Hourly output of alcohol in grams	Per cent of alcohol in condensate
3.2	7.66	6.30
2.7	8.16	6.32
2.3	9.05	5.53
1.94	9.98	5.50
1.65	10.75	4.83
1.04	13.07	3.47

A study of the equilibrium conditions of the reversible reaction

$$C_2H_4 + H_2O \rightleftharpoons C_2H_5OH$$

was made by Stanley, Youell and Dymock.[32] In this instance also a manganese boro-phosphate catalyst was employed[33] and the temperature range was 175° to 250°C.[34] Only atmospheric pressure was maintained during interaction. Equilibrium was approached from both directions, that is, from synthesis of alcohol from olefin and water and from decomposition of alcohol to olefin and water. The constants were calculated according to the equation

$$K_p = \frac{p_{C_2H_5OH}}{p_{C_2H_4} \times p_{H_2O}}$$

Values of the latter, at different temperatures, are given in Table 59.

TABLE 59.—*Equilibrium Constants (K_p) for the Vapor-Phase Hydration of Ethylene.*

Temp. °C.	K_p From synthesis of ethanol	K_p From decomposition of ethanol	Mean
145	6.2×10^{-2}	7.5×10^{-2}	6.8×10^{-2}
175	3.4×10^{-2}	3.8×10^{-2}	3.6×10^{-2}
200	1.59×10^{-2}	1.7×10^{-2}	1.65×10^{-2}
225	1.06×10^{-2}	1.08×10^{-2}	1.07×10^{-2}
250	6.30×10^{-3}	7.08×10^{-3}	6.7×10^{-3}

As shown in Fig. 91, plotting $\log_{10}K_p$ (as ordinates) and $\frac{10^3}{T}$ (as abscissa) a linear relation between the temperature (T) and the equilibrium constant is obtained. This is of the type

$$y = ax + b$$

in which a has a value of 2.1 and b of −6.195. The relationship between K_p and T, therefore, may be written as

$$\log_{10} K_p = \frac{2100}{T} - 6.195$$

Substitution of 380° for T in the above equation gives a value of 1.06×10^{-8} for

---

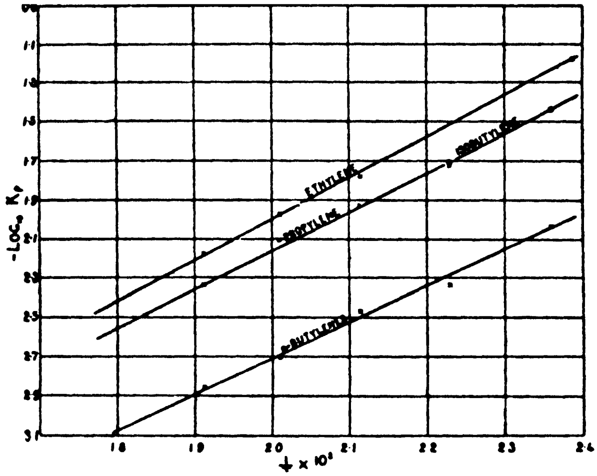
[32] H. M. Stanley, J. E. Youell and J. B. Dymock, *J.S.C.I.*, 1934, 53, 205T; *Chem. Abs.*, 1934, 28, 6362; *J. Inst. Pet. Tech.*, 1934, 20, 488A; *Brit. Chem. Abs.* A, 1934, 1070.

[33] The composition of this material was $MnO \cdot B_2O_3 \cdot xH_3PO_4$, in which x varied from 2.4 to 3.6.

[34] In experiments at 145°C. the catalyst consisted of pumice impregnated with 66 per cent sulphuric acid containing 5 per cent of silver sulphate.

K_p which is in close agreement with the figure obtained by Saunders and Dodge[35] at the same temperature and 70 atmospheres pressure. Stanley and his collaborators calculated (from their data) the heat of hydration of ethylene to be +9600 calories per mole.

Phosphate catalysts have been used by other workers. Dreyfus[36] recommended alkali or alkaline-earth phosphates, such as sodium metaphosphate. Those of tin, lead, cadmium, boron, strontium, beryllium or zinc have been proposed by Horsley.[37] Various mixtures, such as calcium metaphosphate containing a small proportion of the metaphosphates of barium, calcium, strontium, titanium, chromium or tellurium, have been suggested.[38] Other contact agents, which are said to be especially applicable to high-pressure operations at temperatures of 100° to 300°C., are those comprising 1 to 2 moles of the metaphosphate of a trivalent element, such as aluminum[39] or iron,[40] and one mole of a metaphosphate of a divalent metal such as cadmium, nickel, calcium, lead, zinc, copper or tin.



Courtesy Journal of Society of Chemical Industry

FIG. 91.—Relationship of Temperature to Equilibrium Constant for Vapor-phase Hydration of Olefins. (H. M. Stanley, J. E. Youell and J. B. Dymock)

As an illustration, Horsley prepared an acid cadmium phosphate by heating together cadmium oxide and phosphorus pentoxide in the correct proportions to give a material having the composition $CdO \cdot 1.5H_3PO_4$. A mixture of steam and ethylene (in the molar ratio of 3:7) was conducted, at 100 atmospheres pressure and 290°C., over the catalyst in such a manner that the time of contact was one minute. A 3.36 per cent conversion (per pass) of ethylene to ethanol was effected. Some results, obtained under the same conditions of temperature and pressure but with different contact agents, are summarized in Table 60.

TABLE 60.—*Catalytic Hydration of Ethylene.*

Composition of catalyst	Space velocity in reciprocal hours[a]	Alcohol output in grams per liter of catalyst	Per cent conversion of C_2H_4 per pass
$CdO \cdot 1.5H_3PO_4$	([b])	243	3.36
$B_2O_3 \cdot 2H_3PO_4$	6000	155	....
$SrO \cdot 2H_3PO_4$	6000	216	2.69
$FeO \cdot Fe_2O_3 \cdot 8H_3PO_4$[c]	([b])	278	3.46

[a] Space velocity expressed as liters of gas at 20°C. and atmospheric pressure passed per hour over 1 liter of catalyst.

[b] Contact time about 1 minute.

[c] Prepared from ferrous oxalate, ferric oxide, and phosphoric acid.

Liquids, suggested for blending with motor fuels, have been made by the simultaneous hydration and polymerization of mixtures of ethylene and propene.[41] Treatment is effected at high pressures and temperatures of 200° to 350°C. For example, passage of a mixture of 88 volumes of cracking gas and 1 volume of steam (under a total pressure of 120 atmospheres) over a boron phosphate catalyst at 300°C. the time of contact being 1 minute, gave the following products: ethyl alcohol, 46 parts, isopropyl alcohol, 4 parts, acetaldehyde, 0.8 part, and oily liquids, 33 parts.

Dreyfus[42] recommends molten salts of an acidic nature as catalysts. Illustrations of these are fused sodium pyrosulphate or zinc chloride. Other contact agents which have been proposed are the salts of boric, molybdic, tungstic, and vanadic acids[43] and the sulphates of heavy metals.[44] Larson[45] found that hydration of ethylene may be effected at 125-300°C. and 25 to 900 atmospheres pressure in the presence of volatile halides (e.g., hydrogen or ammonium chloride) and an absorbent material, such as activated charcoal.

Oxide Catalysts for Hydration of Ethylene. In an attempt to discover a contact agent for the combination of ethylene and steam, Sanders and Dodge[46] investigated a large number of solid catalysts for the vapor-phase dehydrogenation of ethanol at 360°C. The best was alumina, prepared either by treatment of amalgamated aluminum with water or by precipitation from a solution of sodium aluminate with dilute sulphuric acid. A mixture of tungstic acid and alumina (after reduction with carbon monoxide and hydrogen) was very active but deteriorated somewhat with use. Aluminum silicate, ammonium phosphotungstate and tungstic acid showed a high degree of activity but neither aluminum sulphate nor phosphate was active. Phosphoric acid deposited on pumice was initially a good contact agent but soon lost effectiveness owing to volatilization or formation of volatile compounds. Thoria, precipitated from a solution of the nitrate, did not give satisfactory results.

The best alumina and tungstic acid catalysts were used by Sanders and Dodge for the hydration of ethylene (by an approximately equimolecular proportion of steam) at pressures of 70 to 135 atmospheres and at temperatures of 360° to 380°C. Under these conditions the corrosive action of water vapor became pronounced and reaction tubes of copper, Monel metal or aluminum failed. However, tubes of

Employment of aluminum oxide as a contact agent is reported by Burda.[49] He prepared a material by precipitation with ammonia from an aqueous solution of ammonium alum, redissolving with a strong alkali (e.g., sodium hydroxide), and reprecipitating from the latter solution by neutralization with sulphuric acid. Other metallic oxides which have been recommended are those of zinc or cadmium with which may be incorporated calcium carbonate, alumina or mercury phosphate.[50]

Strongly basic inorganic substances, such as sodium or potassium hydroxide, have been proposed as catalysts by Dreyfus.[51] van Peski and Langedijk[52] observed the vapor-phase hydration of ethylene at temperatures above 100°C. in the presence of one or more metals which may often serve as dehydrogenating agents. Examples of such are platinum, gold, silver, nickel, cobalt, iron, tungsten or vanadium. Compounds of these, e.g., copper phosphate,[53] a mixture of tungstic acid and iron oxide or gold vanadate,[54] may be employed also.

HYDRATION OF PROPENE

Many of the catalysts which have been mentioned as applicable to the hydration of ethylene are also said to be activating agents for the interaction of steam and propene. For example, Remiz[55] reported a 21 per cent yield of isopropanol by hydration of propene at 110°C. in the presence of 54 per cent sulphuric acid containing 3 per cent of silver sulphate. Aqueous solutions of 15 to 60 per cent concentration of non-volatile inorganic acids (sulphuric or phosphoric) are recommended by Metzger.[56] He proposed to conduct a mixture of olefin and steam at temperatures between 170° and 250°C. and pressures above 100 lb. per sq. in. through the liquid catalyst. At higher pressures (up to about 600 lb. per sq in.), more dilute acid and higher temperatures may be employed. The use of excess steam over that theoretically required is said to avoid formation of isopropyl ether. An example of this procedure is the passage of propene and somewhat more than an equimolecular proportion of steam through 27 per cent sulphuric acid at 200°C. and under a gauge pressure of 250 lbs. A condensate containing 20 per cent isopropyl alcohol was obtained. This was equivalent to about 10 per cent conversion of the olefin per pass. Francis[57] advocates that the molecular ratio of olefin to water be not more than 5:1 when using 60 per cent acid, temperature of about 100°C. and pressures of 300 pounds or higher.

Vapor-phase hydration of propene at 120-150°C. in the presence of 20 to 80 per cent sulphuric acid and at olefin partial pressures up to 100 lb. per sq. in. was suggested by Shiffler and Holm.[58] On the other hand a liquid-phase process has been proposed in which the unsaturated hydrocarbon (under pressure) is continuously contacted with aqueous solutions such as 5 per cent phosphoric acid, 6 to 10 per cent sulphuric acid, 15 to 20 per cent aluminum chloride (hexahydrate) or 50

per cent zinc chloride, at temperatures up to 350°C.[59] The aqueous catalyst is continuously separated, isopropanol removed therefrom by distillation, and the liquid then recycled.

In addition to silver sulphate, previously mentioned, other salts may be admixed with sulphuric acid. An illustration of such a composition is an aqueous medium containing 8 per cent zinc sulphate and 3 to 5 per cent of the acid with which may be incorporated also the sulphates of calcium, lead or copper.[60] Reaction vessels made of copper or Monel metal are recommended when these liquids are employed. As an example, a mixture of 35 per cent propene and 65 per cent propane is passed, under 3000 lb. per sq. in., at the rate of 3.34 moles (total hydrocarbons) through 2080 cc. of an aqueous catalyst consisting of 4 per cent zinc sulphate and 1.3 per cent sulphuric acid at 285°C. The reported yield of isopropyl alcohol, based on the olefin used, was 12.9 per cent.

Joshua, Stanley and Dymock advocate solid contact agents such as the acid phosphates or boro-phosphates of manganese, copper, iron, cobalt, uranium,[61] calcium, barium, strontium or magnesium.[62] Some of their results are given in Table 61.

TABLE 62.—*Equilibrium Constants for Vapor-Phase Hydration of Propene.*

Temperature	Values of K_p		
	From synthesis	From decomposition	Mean
175°C.	1.81×10^{-2}	2.00×10^{-2}	1.91×10^{-2}
200°C.	1.16×10^{-2}	1.22×10^{-2}	1.19×10^{-2}
225°C.	7.88×10^{-3}	7.95×10^{-3}	7.92×10^{-3}
250°C.	4.70×10^{-3}	4.57×10^{-3}	4.62×10^{-3}

temperature) a straight line, as shown in Fig. 91, is secured. This linear relation between the equilibrium constant and the temperature may be expressed by the equation:

$$\log_{10} K_p = \frac{1950}{T} - 6.060$$

The heat of hydration of propene, at constant pressure, was computed to be +9000 calories per mole.

A comparison of the data for propene with that for ethylene and the butenes shows that, at a given temperature, equilibrium was less favorable for hydration of propene than for the other olefins. As in the case of ethylene, the best conditions for conversion of propene to propanol-2 are low temperatures and high pressures. Stanley and his collaborators point out that these observations relate only to equilibria and bear no relation to the relative reaction velocities.

Horsley[64] suggested the acid phosphates of boron, beryllium and cadmium as contact agents for operations under pressure and at temperatures of 150° to 300°C. In a process described by Bent and Millar,[65] complete liquefaction of the products of hydration is effected under pressure. The resulting liquid mixture stratifies into an aqueous phase and a hydrocarbon phase. The latter, containing only a small proportion of alcohol, is returned to the reaction zone with more steam. The aqueous layer is removed and subjected to distillation to recover its alcohol content.

HYDRATION OF BUTENES

The work of Marek and Flege[66] on the hydration of butene-2 under 3000 and 5000 pounds pressure in the presence of phosphoric acid on pumice indicated that the main product was butanol-2. The equilibrium constant, K_p, at 482°C. was found to be approximately 2.9×10^{-4}. Stanley, Youell and Dymock[67] have studied the vapor-phase hydration of a mixture of butene-1 and butene-2 using manganese boro-phosphates as catalysts. They also report that butanol-2 was formed from both olefins though a small proportion of butan-2-one and, possibly, butanol-1 was produced. The equilibrium constants for the reaction

$$n\mathrm{C_4H_8} + \mathrm{H_2O} \rightleftharpoons \mathrm{C_2H_5CHOHCH_3}$$

were determined at temperatures of 150° to 250°C. and atmospheric pressure. Stanley and his collaborators assumed that the mixed butenes could be regarded, for practical purposes, as a single compound. The values obtained in these experiments are summarized in Table 63.

TABLE 63.—*Equilibrium Constants (K_p) for Hydration of n-Butenes.*

Temperature	Values of K_p		
	From synthesis	From decomposition	Mean
150°C.	9.6×10^{-3}	9.2×10^{-3}	9.4×10^{-3}
175°C.	4.54×10^{-3}	4.62×10^{-3}	4.58×10^{-3}
200°C.	3.30×10^{-3}	3.42×10^{-3}	3.36×10^{-3}
225°C.	1.95×10^{-3}	1.98×10^{-3}	1.96×10^{-3}
250°C.	1.36×10^{-3}	1.42×10^{-3}	1.39×10^{-3}

A graph of $\log_{10}K_p$ against $\frac{10^3}{T}$ reveals a linear relationship (see Fig. 91) which can be expressed by the equation

$$\log_{10} K_p = \frac{1845}{T} - 6.395$$

The heat of reaction at constant pressure was calculated to be about +8,450 calories per mole.

It would seem that the equilibrium conversions obtainable in the case of the *n*-butenes should be materially lower than those for ethylene, propene or isobutene under the same conditions. Nevertheless, a 25 per cent yield of butanol-2 by vapor-phase hydration of *n*-butene at 225°C. and 200 atmospheres pressure in the presence of an aqueous catalyst has been reported.[68] The latter consisted of a solution containing 8 per cent zinc chloride and 4.7 per cent sulphuric acid. On the other hand, Joshua and his co-workers found the passage of a mixture of 6 moles of the olefin and 4 moles of steam, under a total pressure of 10 atmospheres, over a solid catalyst having the composition $MnO \cdot 0.5B_2O_3 \cdot 2.6H_3PO_4$[69] or that of $CaO \cdot 0.5B_2O_3 \cdot 2.6H_3PO_4$[70] gave only a 0.3 per cent yield of alcohol per pass. In the latter instances the temperature was 240°C. and the gas rate was 4000 liters (measured under standard conditions) per hour per liter of catalyst.

Hydration of Isobutene. It is well known that isobutene (2-methylpropene) can be hydrated to the corresponding alcohol (2-methylpropanol) under milder conditions than are required with the *n*-butenes.[71] For example, dilute nitric acid is a sufficiently active catalytic agent for the iso-olefin but not for the other unsaturated hydrocarbons.

Lucas and Eberz[72] investigated the rate of hydration of isobutene by this acid. They report that it is increased if potassium nitrate is present also. Some of the data obtained are shown in Table 64. For the reaction

$$(CH_3)_2C{=}CH_2 + H_2O \longrightarrow (CH_3)_3COH$$

these workers define the specific reaction constant k by the equation

$$2.3026 \log_{10} (C_o/C_t) = kt$$

in which C_o is the initial concentration (in moles) of the olefin and C_t the concentration after time t (expressed in hours).

It is evident that if $\log_{10}(C_o/C_t)$ be plotted against t, the slope of the curve will be the constant k. The curves (plotted in this manner) for data secured on the

In addition to potassium nitrate, Lucas and Eberz studied the effect of other salts such as lead, cadmium, zinc and mercuric nitrates, copper and nickel sulphates, and manganese chloride. None of these exerted any beneficial influence except mercuric nitrate. In the presence of the latter the solubility of isobutene in dilute

FIG. 93.—Time-Concentration Curves for Hydration of Isobutene at 35°C. (H. T. Lucas and W. F. Eberz)

nitric acid was increased and this was attributed to the formation of a complex, $Hg(NO_3)_2 \cdot C_4H_8$. Also, the free or uncombined olefin in solution was hydrated at a slightly greater rate. Similar observations have been made also with silver nitrate.[72a] That is, the argentic compound and isobutene yielded a complex analogous to that from mercuric nitrate and the olefin, and when this silver derivative was in the acid solution, conversion of the unsaturated hydrocarbon (not in the form of a complex) to alcohol was accelerated.

Eberz and Lucas[73] have measured the equilibrium constants, k_e, for the interaction of 2-methylpropene, $(CH_3)_2CH{=}CH_2$, and water in the liquid phase at 25°C. and 35°C. Their method consisted in dissolving *ter*-butyl alcohol in 0.2N nitric acid and then determining the concentration of unsaturated hydrocarbon and alcohol after at least 24 hours. The values of k_e were found to be 7.48×10^3 (at 25°C.) and 3.9×10^5 (at 35°C.). From these results the free energy change[74] for the reaction

$$C_4H_8(g) + H_2O(1) \longrightarrow C_4H_9OH(1)$$

was calculated as

$$\Delta F^\circ_{298.1} = -1330 \text{ cal. and } \Delta F^\circ_{308.1} = -946 \text{ cal.}$$

Equilibrium between isobutene, trimethyl carbinol and steam in the presence of catalysts of the composition represented by $MnO \cdot BC \cdot 2.4H_3PO_4$ has been studied by Stanley, Youell and Dymock.[75] This was done in two ways: by synthesis of alcohol from olefin and steam, and by decomposition of the alcohol into olefin and water, both operations being conducted at 150° and 175°C. It was observed that the hydrocarbon exhibited a marked tendency to polymerize at temperatures above 180°C. Values of the equilibrium constant (K_p)

$$K_p = \frac{p_{C_4H_9OH}}{p_{C_4H_8} \times p_{H_2O}}$$

are given in Table 66.

TABLE 66.—*Equilibrium Constants for Vapor-Phase Hydration of Isobutene.*

Temperature	From synthesis	From decomposition	Mean
150°C.	3.54×10^{-2}	3.74×10^{-2}	3.64×10^{-2}
175°C.	1.98×10^{-2}	1.98×10^{-2}	1.98×10^{-2}

HIGHER OLEFINS

Little information is available regarding direct hydration of the higher olefins, e.g., pentenes and hexenes. Lucas and Liu[76] effected conversion of 2-methylbutene-2, $(CH_3)_2C{=}CHCH_3$, in the liquid phase at 25° and 35°C., to the corresponding tertiary alcohol employing dilute acids as catalysts. It was observed that reaction proceeded more slowly with this unsaturated hydrocarbon than with 2-methylpropene. However, the rate of reaction was of the first order in both instances. A comparison of the specific reaction constant for these two olefins when using approximately 0.05N nitric acid is shown in Table 67.

Hydrocarbon	HNO_3 (Normality)	$K_{25°}$	$K_{35°}/K_{25°}$	Heat of activation (kg. cal.)
2-Methylpropene	0.0500	0.0667	3.60	23.39
2-Methylbutene-2	0.0532	0.0410	2.83	18.92

Many other acids could be substituted for nitric acid. For concentrations of 0.1M, it was noted that the catalytic activity decreased in the following order: dithionic, sulphuric, hydrochloric, nitric, *p*-toluenesulphonic, picric, oxalic and acetic.

Chapter 12

Direct Esterification of Olefins with Mineral and Organic Acids

The direct combination of olefin hydrocarbons with mineral or organic acids to yield the corresponding alkyl esters is of considerable interest both scientifically and technically. Sulphuric esters, obtained by absorption of olefins in sulphuric acid, constitute important intermediates in the commercial production of the corresponding alcohols. Moreover, alkyl esters of organic acids, such as *sec.*-butyl acetate—normally made by esterification of the alcohol—can be prepared in one stage by treatment of the appropriate olefin with the required organic acid. These addition reactions, many of which are reversible under certain conditions, exhibit interesting features, as, for example, the directive influence of certain solvents or catalysts, especially peroxides, upon the addition of hydrogen bromides to olefins and their derivatives.

According to Markownikov, the addition of halogen acids to olefins tends to occur in such a way that the halogen atom becomes attached to the carbon atom poorer in hydrogen. However, it has for some time been realized that this well-known rule is not rigidly applicable. It has been shown that certain catalysts have a marked influence on the addition of hydrogen bromide to certain olefins, causing the reaction to proceed almost exclusively contrary to the rule of Markownikov. These discoveries, the theoretical implications of which are not yet thoroughly understood, may have an important bearing on the development of modern theories of organic reactions. A brief review of the more recent work along this line is presented under the heading "Peroxide Effect."

ETHYLENE

Reaction with Sulphuric Acid. Ethylene dissolves in concentrated sulphuric acid of about 95-98 per cent concentration at atmospheric pressure (and also in less concentrated acid under increased pressures) to yield both ethylsulphuric acid and diethyl sulphate. The former substance, which is a strong acid, is usually regarded as having the constitution represented by $C_2H_5O—SO_3H$. However, there is evidence for the view that a definite hydrate, $C_2H_5O-SO_3H-H_2O$, exists. Thus, Brooks[1] points out that many of the salts of this acid are hydrated, for example, the barium salt, $Ba(OSO_3—C_2H_5)_2—2H_2O$. Moreover, the reaction velocity between an olefin and 85 per cent sulphuric acid (which undoubtedly contains a substantial proportion of sulphuric acid monohydrate, $H_2SO_4—H_2O$) does not diminish as the reaction proceeds. This fact seems to indicate that there is no increase in the ratio of water to uncombined acid. Brooks also considers that formation of diethyl sulphate probably takes place by interaction of ethylene with hydrated ethylsulphuric acid according to the reversible equation

$$C_2H_5O—SO_3H—H_2O + C_2H_4 \rightleftharpoons (C_2H_5O)_2SO_2 + H_2O$$

---

[1] B. T. Brooks, *Ind. Eng. Chem.*, 1935, 27, 278; *Chem. Abs.*, 1935, 29, 2700; *Brit. Chem. Abs.* B, 1935, 536.

The resulting ester is anhydrous. Also, the above equation indicates that an increase in the water content of the reaction mixture should tend to suppress its formation. This conclusion is in agreement with experimental data. Furthermore, the sensible heat of reaction of a monoalkyl sulphate (RO—SO_3H—H_2O) with an olefin is very small compared with the heat of formation of the monoalkyl sulphate.

Concentrated sulphuric acid and ethylene yield a mixture of ethyl hydrogen sulphate and diethyl sulphate. Appreciable amounts of the latter are present when the acid has reacted with about 0.3 mole of the olefin.[2] Large yields of diethyl sulphate are favored by factors assisting solution of the gas in the acid liquor, such, for example, as high partial pressures of ethylene and the employment of concentrated acid. The influence of pressure on the absorption of ethylene in 97.5 per cent sulphuric acid at 80°C. is discussed by Brooks[3] and summarized graphically in Fig. 94. Here it is shown that under 500 lbs. per sq. in. the amount of ethylene absorbed in 40 minutes was 80 per cent of that required for diethyl sulphate formation, whereas at 100 lbs. pressure scarcely 30 per cent was absorbed. Diethyl sulphate formation is sharply suppressed by the use of more dilute sulphuric acid, as is evident from the curves in Fig. 95. In this instance, agitation of ethylene under 450 lbs. pressure with 97.5 per cent acid for 40 minutes yielded over 70 per cent of the theoretical of the dialkyl ester and operation with 93 per cent acid (under similar conditions) furnished only 35 per cent of this ester.

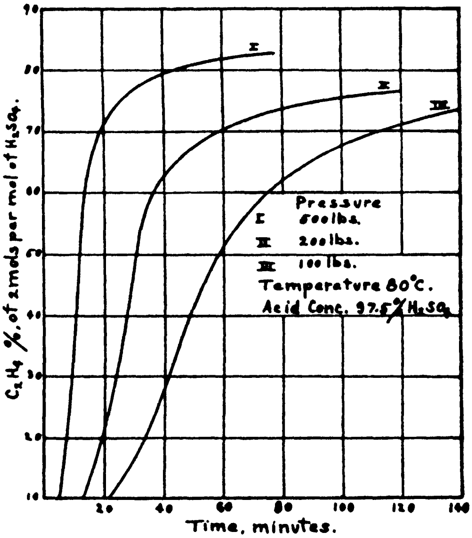

FIG. 94.
Influence of Pressure on Absorption of Ethylene in Sulphuric Acid at 80°C. (B. T. Brooks)

Courtesy Industrial and Engineering Chemistry

Strahler and Hachtel[4] report that 1 kg. of sulphuric acid (d. 1.83) at 70°C. will absorb 400 g. of ethylene, under 15 atmospheres pressure. The products consist of 75 per cent of ethylsulphuric acid and 25 per cent of the dialkyl ester. The latter may be prepared also by heating ethyl hydrogen sulphate under reduced pressure so that the neutral ester is continuously distilled off. This latter step, removal of one of the products, is necessary since the reaction is a reversible one.

---

$$2C_2H_5O{-}SO_3H \rightleftharpoons (C_2H_5O)_2SO_2 + H_2SO_4$$

Dilution with water separates diethyl sulphate from acid liquor as a non-aqueous layer. When recovered sulphuric acid is employed, this simple removal of the product is hindered by suspended carbonaceous material. In such cases water-immiscible solvents, e.g., diethyl ether, have been proposed as extraction agents.[5]

Diethyl sulphate functions as an ethylating agent in many industrial syntheses. Although stable when dry, it undergoes slow hydrolysis in the presence of moisture. For this reason, iron containers to be used for storage or transportation of the ester should be thoroughly dried. Such treatment is particularly recommended by Siebeneicher[6] who investigated an explosion caused by neglect of this precaution.

In one process for producing alkyl esters from olefins and strong acids (such as sulphuric, phosphoric or certain sulphonic acids)[7] the reactants are intimately mixed and simultaneously cooled so as to eliminate the desired products from the reaction zone immediately after formation. For close contact, the components in the liquid state may be passed through a rapidly rotating apparatus.

Reaction with Halogen Acids. Unlike its immediate homologues, ethylene does not appear to combine with the anhydrous halogen acids in the absence of contact agents. For the vapor-phase reaction, sublimed anhydrous aluminum chloride mixed with an equal part of asbestos has been found active, but its catalytic power rapidly declines with use. For example, a 40 per cent conversion of ethylene into ethyl chloride at 80°C. was readily obtained but the catalyst gradually became impregnated with a viscous, syrupy polymerization product which markedly reduced its activity.[8]

at 170-230°C. in the presence of bismuth trichloride supported on silica gel have been determined by Rudkovskii, Trifel and Frost.[9] The variation with absolute temperature of the observed equilibrium constant,

$$K_p = \frac{p_{\mathrm{HCl}} \times p_{\mathrm{C_2H_4}}}{p_{\mathrm{C_2H_5Cl}}}$$

could be expressed as follows:

$$\log K_p = 4.96 - \frac{2925}{T}$$

From this equation the heat of reaction was calculated as 13.4 cal. per mole. Activation-energy calculations, carried out by Sun and Liu,[10] show that the reactivities of the hydrogen halides with respect to ethylene increase in the same order as their molecular weights. These findings are said to be in agreement with experimental results.

For combining olefins with halogen hydrides special types of catalysts developed by Strange and Kane are:

(1) An adsorptive material having a microporous structure (such as active carbon or silica gel);[11]
(2) Adsorptive metal-oxide gels (prepared by partially dehydrating a hydrogel or gelatinous precipitate);[12]
(3) A porous catalyst mixed with a heat-absorbing material (such as a mixture of silica gel, hydrated alumina and iron turnings.[13]

When using these activators, the mixture of gases is passed over them at temperatures up to the boiling point of the product. The resultant alkyl halide is recovered by distillation of the products; this may be carried out under reduced pressure.

Reilly[14] employs an anhydrous liquid medium such as ethyl chlorosulphonate (which may also contain bismuth chloride) to effect addition of gaseous ethylene and hydrogen chloride at 40-70°C. Liquid catalysts, such as a solution of ferric chloride in ethyl chloride, or of aluminum chloride in nitrobenzene, have been suggested for this vapor-phase reaction.[15]

Hjerpe and Gruse[16] produce ethyl chloride by passing the reaction mixture at atmospheric pressures over aluminum chloride or bismuth trichloride. For example, refinery or cracking gas is fractionated under pressure and the low boiling cut, containing mainly methane, ethylene (about 10 per cent) and ethane is mixed with hydrogen chloride. The resulting composition should contain approximately equal volumes of olefin and hydrogen halide. This is heated to 350°F. and conducted over aluminum chloride, the time of contact being about 1 to 2 minutes. Ethyl chloride is recovered by scrubbing the gases with a relatively non-volatile petroleum absorbent oil from which it is afterwards separated by distillation. Zinc halides distributed on a supporting medium have been proposed also.[17] Balandin and Livanova[18] obtained a 62 per cent yield of the ester using barium chloride as the contact agent. They observed no reaction at temperatures below 210°C., although above 300°C. dissociation of ethyl chloride occurred.

Alkyl halides may be prepared also by conducting the gaseous mixture of olefin and hydrogen halide countercurrent to an aqueous solution of a metallic halide, such as antimony or bismuth trichloride. (See Fig. 96.) The alkyl halide is subsequently recovered from the solution of catalyst, which is continuously recycled.[19] It is reported that in this method of operation the concentration of the metallic halide may be so adjusted that olefins may be selectively absorbed from gaseous mixtures, those of higher molecular weight being removed first. To illustrate, cracking gas was mixed with 5 per cent more hydrogen chloride than required theoretically to combine with the olefins present. The gases were then conducted through four consecutive towers countercurrent to the streams of catalysts which were 45, 75, 90 and 95 per cent solutions, respectively, in concentrated hydrochloric acid. The temperature in the first three towers was 25°C. and in the last one was 55°C.; each of the former was followed by a trap maintained at 0°C. The products obtained from each unit (tower and trap), in order of increasing concentration of catalyst, were as follows: (a) almost pure amyl chloride; (b) amyl, butyl and propyl chlorides in the ratio 12:21:8, by weight; (c) these same chlorides, but in the ratio 5:19:8; and (d) butyl and propyl chlorides in the ratio 21:15. Ethylene was the only olefin in the residual gas.

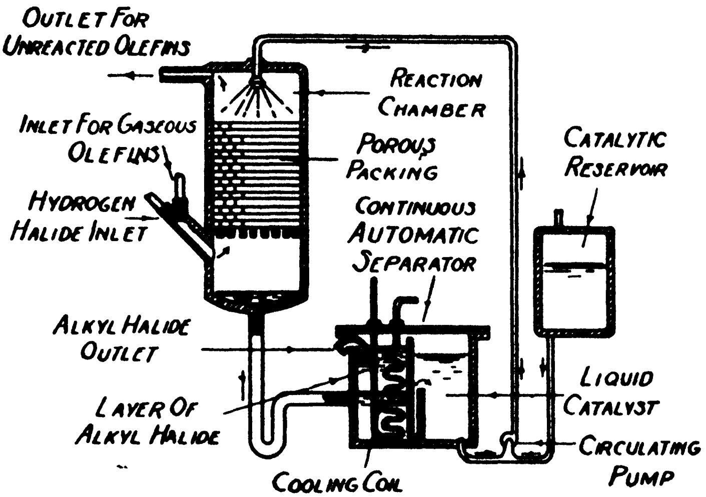

FIG. 96.—Sketch of Method for Preparation of Alkyl Halides with Metallic Halide Catalysts. (H. S. Nutting, P. S. Petrie, D. H. Croope and M. E. Huscher)

According to Tulleners, Tuyn and Waterman,[20] combination of ethylene with hydrogen chloride takes place rapidly and almost quantitatively at −80°C. in the presence of aluminum chloride suspended in ethyl chloride as a diluent. Under these conditions, the olefin is quickly absorbed at normal pressure with practically no formation of by-products. The reaction is virtually carried out in the liquid phase. Using ethylene at atmospheric pressure, a decrease in reaction velocity was noted on raising the temperature to —40°C. and practically no combination took place at —15°C.

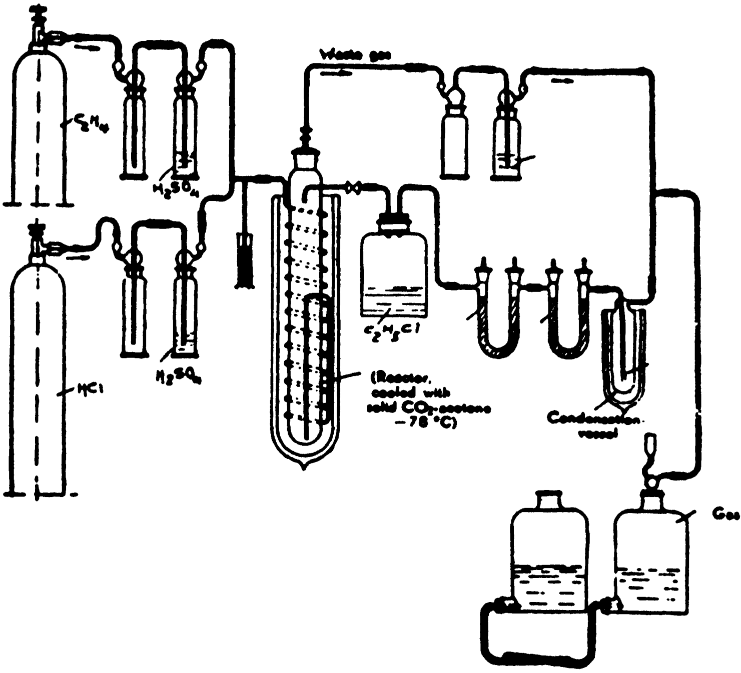
Working on a small scale, the best results were obtained using the apparatus sketched in Fig. 97. Ethylene and hydrogen chloride gases, after drying with concentrated sulphuric acid, are mixed and passed through a precooling spiral coiled around the reaction tube which is cooled, as indicated, in a paste of solid carbon dioxide and acetone.[21] The gases, entering the reaction vessel just above the bottom, come in contact with a mixture of aluminum chloride and ethyl chloride. After the discharge of air from the reaction tube, the level of the liquid gradually rises and the product can be run off into a receiver. Gentle warming (not above 12.6°C., the boiling point of ethyl chloride) liberates dissolved gases, from which hydrogen chloride is extracted by soda lime, and ethyl chloride is further recovered in the condenser (cooled to —78°C.). Large gas bottles at the end of the system take care of waste gases and unused ethylene. (The ethylene supply contained 92.6 per cent ethylene, with no higher olefins present.)



Courtesy Recueil des Travaux chimiques des Pays-Bas

FIG. 97.—Apparatus for Reaction of Ethylene and Hydrogen Chloride. (A. J. Tulleners, M. C. Tuyn and H. I. Waterman)

[21] Tulleners, Tuyn and Waterman note that gasoline fractions can be used instead of alcohol or acetone in the preparation of the cooling medium.

In operation hydrogen chloride gas is admitted first to give the slight excess that favors rapid reaction, and then currents of the two gases (in about equimolecular proportions) are used. The reaction tube at the beginning of a run contains 40 g. of ethyl chloride and 10 g. of aluminum chloride. With a glass reaction vessel of 300 cu. cm. capacity, 180 liters of ethylene could be converted quantitatively into ethyl chloride within 1 hour. Operations on a semi-commercial scale could be carried out in an apparatus constructed of copper as this metal proved resistant to corrosion. On the other hand an iron reaction chamber, possibly because it was more readily corroded, seemed to exert a poisoning action on the catalyst.

With aluminum bromide as catalyst, ethylene and hydrogen bromide reacted smoothly and rapidly at —80°C., furnishing a good yield of ethyl bromide. In the absence of the metallic bromide this olefin does not react with liquid hydrogen bromide at room temperature although propene is rapidly converted under these conditions.[22]

An indirect method of producing alkyl halides, particularly ethyl chloride, has been described by Calcott and Daudt.[23] They continuously contact the absorption product of the olefin in sulphuric acid with an aqueous solution of a hydrogen halide in the liquid phase at temperatures above 100°C. Evolved vapors and also a portion of the liquid reaction product are continuously withdrawn and treated for the recovery of the alkyl halide.

Reaction with Organic Acids. The direct esterification of ethylene with organic carboxylic acids appears to be more difficult than in the case of the higher olefins. In a general way it is to be expected that this reaction, will be favored by the use of elevated pressures and moderate temperature, when operating in the gas phase.[24] Catalysts are usually essential for good yields and these include strong acids, such as sulphuric and phosphoric, as well as zinc chloride and other inorganic salts. In a process described by Graves,[25] an olefin (such as ethylene) and an organic acid (e.g., acetic) are continuously passed through concentrated sulphuric acid, saturated with the olefin. The temperature of the liquid is maintained above the boiling point of the desired ester. In the case of ethyl acetate 140°C. is sufficient. The effluent vapors are condensed and the ester separated from the condensate. Deterioration of sulphuric acid is retarded by circulation through a filter to remove suspended carbonaceous material.

According to Dreyfus,[26] ethyl esters of the lower aliphatic acids may be produced by contacting ethylene with the organic acid either in the liquid or gaseous phase. Temperatures of 350-550°C. are used and pressures of at least 5 atmospheres in the absence of strong mineral acids. For making ethyl acetate (and simultaneously some alcohol) a mixture of approximately 3 volumes of ethylene, 2 volumes of stearic acid and 1 volume of acetic acid is heated to 450°C. and repeatedly conducted over pumice. The last operation is effected under a pressure of 20 atmospheres. The products are afterwards separated by fractional distillation. As a modification, the vapors of petroleum hydrocarbons (boiling 200-350°C.) admixed with acetic acid are subjected to pyrolysis at 700°C. and atmospheric pressure in the absence of a catalyst. The resulting gases are cooled to

400°C., compressed to 400 atmospheres pressure, and conducted over pumice impregnated with phosphoric acid.[27]

A method developed by Edlund and Evans[28] comprises reacting the olefin and organic acid in the presence of sulphuric acid and then allowing the reaction products to stratify as an ester-containing solvent phase and an acid layer. After separation, the ester is recovered by distillation. Unreacted olefin may serve as the solvent, or a saturated hydrocarbon (*e.g.*, butane or pentane) to serve in the latter capacity can be added to the reactants.

Another procedure involves hydrolyzing diethyl sulphate to ethyl alcohol, ethyl sulphuric acid, and sulphuric acid.[29] A calcium salt of a fatty acid, e.g., calcium acetate, is then incorporated, the quantity of salt being equivalent to about 80 per cent of the alkyl radical present, and the mixture distilled. In this manner a 94 per cent yield of ethyl acetate is said to be obtained from diethyl sulphate. In some instances acetic acid may be substituted for the calcium salt.[30] In such cases this process is applicable not only to the manufacture of ethyl acetate but also to the corresponding isopropyl and butyl esters.

The recovery of pure alkyl esters from the reaction products of calcium acetate and an acid liquor obtained by absorption of olefins in sulphuric acid, is described by Lebo and Beamer.[31] The mixture, after addition of some alcohol, is distilled and the condensed ester vapors are returned to the still: the operation is continued until water-formation practically ceases. When this occurs the ester vapors are subsequently conducted to a second stage where they are mixed with steam, and washed with water, and dried.

Young[32] reports the formation of organic cyanides by treatment of a solution of olefin in an inorganic acid (sulphuric or hydrohalogen) with sodium cyanide at 20°C.

PROPENE

The products of reaction between propene and sulphuric acid are isopropylsulphuric acid, $(CH_3)_2CHO—SO_3H$, and diisopropyl sulphate, $[(CH_3)_2CH]_2SO_4$. Both of these are intermediates in the commercial production of isopropanol. No *n*-propyl esters are formed in this reaction.[33]

In one commercial process, a gas containing propene is absorbed at normal pressure in 90 per cent sulphuric acid. An absorbent oil is added to increase the rate of solution of the gas. Operation is continued until the acid product contains a substantial proportion of diisopropyl sulphate. A product consisting mainly of the dialkyl sulphate is obtained when mixtures of propane and propene are agitated under pressure with about 85 per cent sulphuric acid or by contacting gaseous propene at 10-40°C. under pressures over 50 pounds per sq. in. with 65-85 per cent sulphuric acid, or, at 25°C. under 100 lbs. pressure with 80 per cent acid.[34] Under such conditions the formation of polymers is reported as almost entirely avoided. Absorption of gaseous propene in more concentrated sulphuric acid at low temperatures may also be employed.[35]

As in the case of ethylene, it seems likely that the initial reaction product between aqueous sulphuric acid and propene is a hydrated monoisopropyl ester, which subsequently reacts with more hydrocarbon to form water and the neutral di-ester, according to the following equations:

$$C_3H_6 + H_2SO_4(H_2O) \longrightarrow (CH_3)_2CHO{-}SO_3H{-}H_2O$$
$$C_3H_6 + (CH_3)_2CHO{-}SO_3H{-}H_2O \longrightarrow H_2O + (iso\text{-}C_3H_7{-}O)_2{-}SO_2$$

Evidence for the existence of the monoalkyl esters in a hydrated condition has already been presented in reference to ethylene[36]

Reaction with Halogen Acids. In the absence of specific catalysts, hydrogen chloride does not react with propene in the gaseous phase even at pressures as high as 105 atmospheres and temperatures up to 105°C. In the liquid phase, however, combination takes place fairly readily, the main product (isolated by Maass and his co-workers[37]) being isopropyl chloride, although some hexyl chloride was formed, particularly at lower temperatures. Later, Maass and Sutherland[38] investigated the velocity of reaction with rise in temperature when the reactants were maintained in the liquid state. Using a mixture of 2 moles of hydrogen chloride and 1 mole of propene (this mixture having a critical temperature of 70°C.) they found the velocity in liquid phase experiments to increase regularly with rising temperature up to about the critical temperature, above which it was uniformly zero.

In the presence of certain catalysts, however, hydrogen chloride readily combines with propene in the gas phase at atmospheric pressure. Brouwer and Wibaut[39] showed that, although this reaction was slow at room temperature in the presence of pure silica gel, its rate was markedly increased if the gel was impregnated with certain metallic chlorides. Examples of the latter are ferric chloride, bismuth chloride or zinc chloride which were efficient catalysts at room temperature but much less so at 80°C. At this higher temperature impregnation with mercuric, nickel, aluminum or calcium chloride was found effective. The reaction product consisted of about 97 per cent isopropyl chloride with a small proportion of higher-boiling products, probably hexyl chloride. No *n*-propyl chloride could be detected. The presence of oxygen in the reacting gases did not affect the course of the reaction. The peroxide effect (*q.v.*) was not observed when liquid hydrogen chloride combined with propene (to form only isopropyl chloride) in the presence of benzoyl peroxide.

A liquid mixture of propene and hydrogen bromide undergoes fairly rapid reaction even at room temperature. However, it has been shown by Ipatieff, Pines and Wackher[40] that no action occurs when pure propene gas is passed through a solution of hydrogen bromide in glacial acetic acid at 5°C. Certain organic compounds, such as hexane, cyclohexane, benzene and organic bromides, greatly accelerated the combination in acetic acid solution although polar compounds, such as

water, alcohol and acetic acid, had no promoting effect. A rapid reaction was also observed when an equimolecular gaseous mixture of propene and hydrogen bromide was conducted through hexane. Ipatieff and his collaborators concluded that union between olefins and hydrogen bromide in the liquid phase is autocatalytic since the bromides formed during the reaction exert a definite catalytic influence. According to Sorokin, Belikova and Bogdanova,[41] the product of the action of propene on hydrogen bromide in glacial acetic acid solution is isopropyl bromide admixed with some *n*-propyl bromide.

In the method proposed by Strange and Kane,[42] propene and hydrogen chloride (or bromide) are contacted in the gaseous phase at a temperature below the normal boiling point of the resulting ester, e.g., at 80-120°C., with a solid porous adsorbent having a large surface area. Examples of such are silica gel or hydrous alumina mixed with iron turnings. The ester formed is periodically recovered from the catalyst mass by distillation under reduced pressure. Other adsorbent catalysts used by Strange and Kane[43] for this reaction include alumina gel prepared by co-precipitation of sodium aluminate and aluminum chloride in water, followed by drying at 150°C. for 2 hours and then at 250-300°C. for 2 hours more. Ferric chloride, vanadium or cerium salts may replace aluminum chloride, and alumina may be substituted by aluminum silicates or tin tungstates. The use of dehydrated alumina is described by Gayer.[44]

Lazier[45] made alkyl fluorides, such as propyl fluoride, by a vapor-phase combination of an olefin with hydrogen fluoride at elevated pressures and high temperatures. The catalysts employed were fluorides of multivalent elements such as manganese, cobalt, iron, aluminum or zinc. Thus, propyl fluoride is prepared by treatment of propene with gaseous hydrogen fluoride at 50 atmospheres and 250°C. with a contact agent consisting of activated charcoal impregnated with zinc fluoride. By carrying out the reaction in an inert solvent, such as dichloromethane or carbon tetrachloride, hydrogen fluoride may be added to unsaturated compounds having no triple linkings.[46] For example, products that may serve as insecticides or as textile auxiliaries are obtained by combining hydrogen fluoride with oleic or undecenoic acid, or with an olefin having at least 10 carbon atoms; *e.g.*, dodecene, $C_{12}H_{24}$.

Reaction with Organic Acids. Direct union of propene with various organic carboxylic acids appears to take place fairly readily in the liquid phase in the presence of certain catalysts. Sulphuric acid was used by Coleman[47] for direct esterification of olefins with anhydrous saturated carboxylic acids under superatmospheric pressures. Such a treatment of propene with glacial acetic acid assisted by sulphuric at about 125°C. produced isopropyl acetate. Metallic salts of strong acids (e.g., zinc chloride) were employed by Brezinski and Frolich[48] for esterification of olefins at 100-300°C. under pressures above 250 lb. per sq. in. Reaction may be carried out in an autoclave lined with aluminum or a non-corro-

sive alloy steel. At 150°C. under pressure approximately equimolecular proportions of propene and anhydrous acetic acid (containing a small proportion of acetic anhydride) and zinc chloride gave a 12.5 per cent yield of propyl acetate.

Boron fluoride has been shown by Dorris, Sowa and Nieuwland[49] to be an excellent catalyst for the liquid phase esterification of olefins under such mild conditions as 70°C. and pressures of about 25 cm. of mercury above 1 atmosphere. The isopropyl esters of acetic, monochloroacetic, dichloroacetic, trichloroacetic and benzoic acids were obtained in yields of 7, 34.2, 39.5, 48.4 and 88 per cent, respectively, by reacting propene with acids under conditions just given. Combination of propene with salicylic acid in the presence of boron trifluoride yields mainly 2-hydroxy-3-isopropylbenzoic acid and also the isopropyl ester. At the same time some isopropyl-2-hydroxy-3,5-diisopropylbenzoate is also produced. This suggests that isopropyl salicylate is first formed but undergoes further rearrangement and reaction with propene.[50]

Vapor-phase combination of olefins, such as propene, with aliphatic saturated monocarboxylic acids is effected by Strange and Kane[51] with the aid of metal salts of a strong mineral acid (such as the chlorides, bromides, phosphates or sulphates of zinc, aluminum, mercury, copper, cadmium, bismuth or antimony), or of a non-volatile strong mineral acid (sulphuric or phosphoric) or acidic derivative of such acids, e.g., sodium acid sulphate or benzene sulphonic acid. For example, 15 to 20 per cent yields of isopropyl acetate are secured by conducting approximately equal parts of propene and acetic acid vapor, at 110°C. and atmospheric pressure over a catalyst at the rate of 2 g. per cc. of catalyst per minute. The latter was prepared from 500 parts of adsorbent carbon and 50 parts of 75 per cent phosphoric acid, and dried at 150-250°C.[52]

BUTENES AND HIGHER ALIPHATIC OLEFINS

The higher olefins may be classified according to their behavior with sulphuric acid into two main groups, namely:

(a) Tertiary, or isoolefins, such as isobutene, trimethylethylene and 2-methylbutene-1, which react vigorously with relatively dilute (about 60 per cent) sulphuric acid and exhibit a marked tendency to polymerize with more concentrated acids;

(b) Secondary olefins, such as butene-1, butene-2, pentene-1, pentene-2, and hexene-2, which yield esters of secondary alcohols on sulphation with moderately concentrated sulphuric acid.

Isoolefins. The isoolefins, exemplified by isobutene, yield tertiary alcohols on absorption in sulphuric acid of 50-70 per cent concentration and subsequent hydrolysis of the alkyl sulphuric esters. So far as can be ascertained the corresponding di-esters have not been prepared since considerable polymerization occurs under conditions favoring their formation (i.e., use of more concentrated acids). This condensation may be prevented by the presence of metal cyanides or complex cyanides, or soluble platinum, copper, iron, cobalt, nickel or silver salts.[53] For changing isobutene into *ter.*-butyl sulphuric acid, use of acid concentrations of

[52] Reaction of propene with sulphuric acid and its application in the commercial production of isopropanol are discussed in Chapter 14.

[53] Dutch P. 31,611, 1933, to Bataafsche Petroleum Maatschappij; *Chem. Abs.*, 1934, 28, 2368.

55-65 per cent at 10-35°C.[54] or 65 per cent at 10-15°C.[55] is advocated. Under these conditions the isobutene is selectively absorbed and any accompanying straight-chain butenes are recovered unchanged.

Secondary Olefins. For conversion of secondary olefins, such as the *n*-butenes, into their sulphuric acid esters, acid concentrations of 70-85 per cent at temperatures below 30°C. have been usually recommended. Under moderate pressures the hydrocarbon can be contacted in liquid form with the sulphuric acid. In this way butene-1 and butene-2 give esters of butanol-2 but pentene-1 yields esters of pentanol-2 exclusively. On sulphation of pentene-2 a mixture of esters derived from pentanol-2 (65 per cent) and pentanol-3 (35 per cent) is obtained.

Sulphation of isopropylethylene might be expected to yield esters of 3-methylbutanol-2. Actually, however, the initial product is the sulphuric ester of *ter.*-amyl alcohol, which, in the presence of acid concentrations necessary to react with this type of olefin, undergoes rapid polymerization.[56]

Mainly dialkyl esters derived from secondary alcohols having 4 or more carbon atoms are obtained by treating 90-100 per cent sulphuric acid with an excess of the corresponding olefin. The latter should be previously freed from tertiary olefins by treatment with 65-70 per cent sulphuric acid. Also reaction temperatures and pressures should be sufficiently low to maintain the olefin in liquid form.[57] Dibutyl sulphate is readily prepared in this way from the *n*-butenes.[58] Dialkyl sulphates of this type, formed during the sulphation of olefins for the production of the corresponding alcohols, separate from the acid liquor as an immiscible liquid phase on dilution with water.[59] They can be reconverted into the alkylsulphuric ester by heating with a 60-85 per cent aqueous solution of sulphuric acid.[60] Lacy[61] reports the production of dialkyl esters by absorption of ethylene homologues in sulphuric acid of about 75 per cent concentration followed by the addition of sufficient primary alcohol, such as ethanol, to satisfy the reactivity of the remaining sulphuric acid.

The purification of dialkyl sulphates by a process which includes their final distillation in the presence of less than 10 per cent sulphuric acid has been disclosed by Cox and Carruthers.[62] According to Brooks,[63] *sec.*-diamyl sulphate, a substance not hitherto known, can be prepared in 70-75 per cent yields by treating 90 per cent sulphuric acid at 15-20°C. with an excess of pentene-2. Dilution with water effects separation of the neutral ester and dissolved pentene-2.

Bertsch has made alkyl esters of persulphuric acid by reaction of the acid on high molecular weight olefins, such as hexadecene.[64]

Lee[65] has described the production of alkyl thiocyanates by treating the sulphuric acid ester of a secondary or tertiary alcohol with an alkali sulphocyanide.

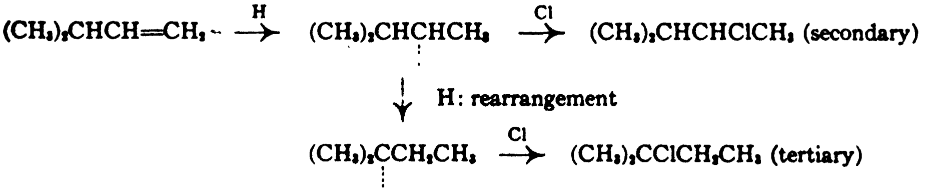
For example, amylene is absorbed in 60 per cent sulphuric acid. To the resulting acid liquor, at 0°C., is added sodium thiocyanate. The product has a boiling range of 165-170°C.

Reactions of Tertiary Olefins. The tertiary olefins combine much more readily with hydrogen halides than do the isomeric secondary olefins. Leendertse, Tulleners and Waterman[66] found that both trimethylethylene and asymmetric methylethylethylene (2-methylbutene-1) combine readily at —80°C. with hydrogen chloride in the absence of catalysts. Under these conditions pentene-1 and pentene-2 react much more slowly and isopropylethylene practically not at all. Without catalysts at —80°C. the same reaction product, namely, *ter.*-amyl chloride or 2-chloro-2-methylbutane, was obtained from both of the branched chain pentenes while pentene-1 furnished a monochloropentane the structure of which was not determined. The union of these pentenes with hydrogen chloride at —80°C. was greatly accelerated by aluminum chloride in the presence of which pentene-2 yielded about 40 per cent of chloropentanes (boiling at 95-97°C.) and 60 per cent of monochlorides derived from the trimer, $(C_5H_{10})_3$. Under similar treatment, trimethylethylene and 2-methylbutene-1 gave a mixture of 2-chloro-2-methylbutane and monochlorides derived from the trimers of these olefins. The reaction of hydrogen chloride with isopropylethylene at —80°C. in the presence of aluminum chloride produced much 2-methyl-3-chlorobutane, together with a mixture of monochloro compounds formed by addition of hydrogen chloride to the olefins obtained by polymerization. On the other hand, Whitmore and Johnston[67] have found that the addition of hydrogen chloride to isopropylethylene in the dark at room temperature gives 88 per cent of a mixture of about equal amounts of tertiary and secondary amyl chlorides. The secondary chloride, recovered from the mixture after hydrolysis of the tertiary ester, boiled at 91.9°C. under 736 mm. and was stable when heated for 24 hours at 100°C. It did not react with water at room temperature. This addition reaction, according to Whitmore and Johnston, may be represented as



$$\begin{array}{lcl}
(CH_3)_2CHCH{=}CH_2 \xrightarrow{H} (CH_3)_2CH\dot{C}HCH_3 & \xrightarrow{Cl} & (CH_3)_2CHCHClCH_3 \text{ (secondary)} \\
\quad\quad\quad\quad \Big\downarrow \text{H: rearrangement} & & \\
(CH_3)_2\dot{C}CH_2CH_3 & \xrightarrow{Cl} & (CH_3)_2CClCH_2CH_3 \text{ (tertiary)}
\end{array}$$

The formation of a tertiary ester from isopropylethylene and hydrogen chloride is therefore the result of an intramolecular rearrangement similar to that occurring during the sulphation of this olefin.

From the mixture of amylenes and diolefins present in the fraction of vapor-phase cracked gasoline boiling at 30-42°C., the tertiary olefins, as well as the diolefins, are removed almost quantitatively by treatment with 37 per cent aqueous hydrochloric acid. Moor and Katzman[68] investigated this reaction and obtained their best results by using 2 moles of hydrochloric acid per unit of hydrocarbon fraction at 0-20°C. Above 20°C., polymerization is increased and reaction is much slower at —10°C. This treatment converted the tertiary amylenes into *ter.*-amyl chloride and largely polymerized the diolefins present, so that the residual unchanged hydrocarbons consisted mainly of secondary olefins. Moor and Katzman effect combination of the secondary amylenes (remaining after treatment with the aqueous acid) with hydrogen chloride in the gas phase at 115-120°C. using bismuth chloride on glass wool as a catalyst. Under these conditions the yield of secondary chlorides was 90 per cent. This decreased to 50 per cent at 100°C. and 21 per cent at 170-180°C. The bismuth chloride catalyst was slowly poisoned due to the formation of polymerized chloro hydrocarbons. By a combination of these two Moor and Katzman procedures, i.e., treatment with aqueous acid followed by that with gaseous hydrogen chloride, the total yield of secondary and tertiary amyl chlorides was 74 per cent of the initial material, the theoretical yield on this basis being 82 per cent.

Triisobutylene can be directly combined with hydrogen chloride at —78°C. in the absence of a catalyst.[69] The resulting chloride, however, is not very stable. This instability may be an explanation of the low, and sometimes even negative, bromine values observed for polymerized hydrocarbons.

Aromatic vinyl compounds, such as styrene, easily react in the liquid phase with hydrogen chloride in the presence of substances capable of forming readily dissociable addition compounds with the hydrogen halide.[70] Examples of such are dimethyl aniline and other amines, acetone and methyl alcohol. Under these conditions styrene may be converted into α-chloroethylbenzene, $C_6H_5CHClCH_3$, Water may serve as a catalyst also if it is present in an extremely finely divided state.[71]

Tuot[72] has examined the reaction products of a number of higher monolefins with hydrogen bromide at 0°C. and from these has isolated a number of monobromo compounds. These together with some of their physical properties are given in Table 68. The bromides were readily hydrolyzed to the corresponding alcohols whose boiling points were 40 to 50°C. higher than those of the present olefins. This investigator also points out that the olefins suspended in dilute sulphuric acid are converted into non-distillable bromides by a mixture of potassium bromide and bromate.

Reactions with Organic Acids. Olefins, such as isobutene and trimethylethylene, which give tertiary alcohols on hydration, combine with organic acids much more readily than their less branched isomers. Good yields of tertiary alkyl acetates may be obtained by reacting the olefin with the organic acid at room temperature in the presence of a small proportion of sulphuric acid as catalyst. For example, in the production of *ter.*-amyl acetate from isoamylene and acetic acid (containing some acetic anhydride) only a small proportion of sulphuric acid is employed, thus reducing polymerization of the olefin to a minimum.[73] Combination of anhydrous formic acid with the pentenes and hexenes present in the light fractions of cracked benzine takes place slowly without catalysts.[74] However, concentrated sulphuric acid (in small proportions) greatly accelerated the reaction although it later caused some decomposition of the esters. Rapid ester formation without appreciable polymerization was attained by repeatedly recycling the hydrocarbon material through the carboxylic acid containing a limited quantity of sulphuric acid.

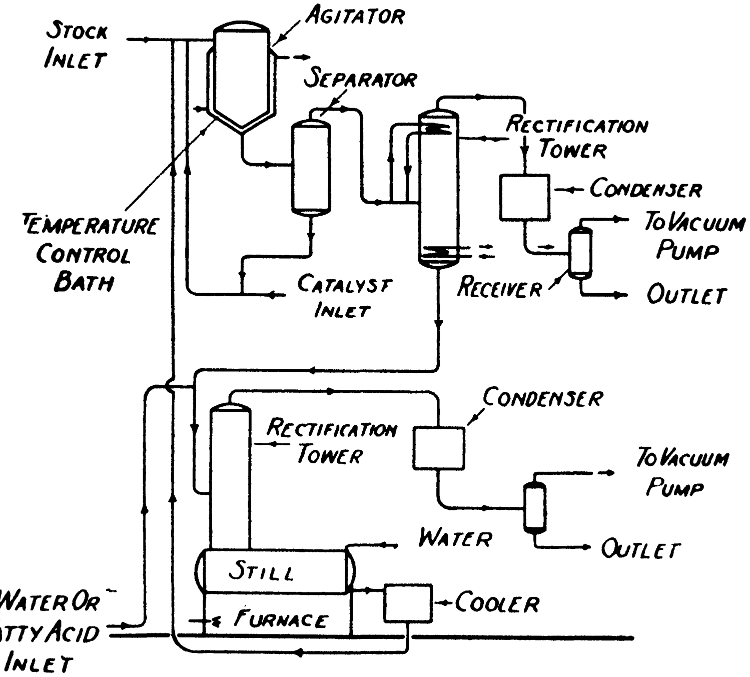

Fig. 98.—Flow Diagram of Method of Producing Alcohols and Esters from Olefins. (H. E. Buc)

The conversion was carried out as a continuous distillation process by allowing the olefin-bearing vapors to react in a side-tube with anhydrous formic acid in the presence of a small quantity of sulphuric acid. The esters were thus returned, immediately on formation, to the distilling flask. Polymerization of the olefins was in this way avoided and decomposition of the esters by the sulphuric acid minimized. Secondary and tertiary amyl and hexyl formates were produced almost quantitatively.

Direct union of some of the more reactive monolefins with strong organic acids, such as the chloroacetic acids, is known to occur readily in the absence of catalysts. Quantitative yields of *ter*-amyl chloroacetates were obtained by Nernst[75] at 30°C. although an equilibrium mixture of olefin and ester resulted at 100-150°C.

The influence of high pressures on reactions of the above type has been studied by Fawcett and Gibson.[76] At 30°C. from equimolecular proportions of trimethylethylene and trichloroacetic acid, they obtained (after 16 hours) yields of 18.6 per cent and 33.9 per cent of tertiary esters at 1 atmosphere and 3,000 atmospheres, respectively. From equimolecular proportions of bromethylethylene and acetic acid (without a catalyst) at 100°C., the ester yields in 16 hours were 1.1 per cent at atmospheric pressure and 6.6 per cent at 3,000 atmospheres. The corresponding figures for tests at 110°C. were 0.4 per cent and 4.5 per cent, respectively. A number of results by Fawcett and Gibson on the direct esterification of cyclohexene (2 moles) with trichloroacetic or dichloroacetic acid (1 mole) are summarized in Table 69.

TABLE 69.—*Non-Catalytic Esterification of Cyclohexene*

Acid Used	Temp., °C.	Time, Hrs.	Pressure, Ats.	Per Cent Acid Esterified

" "	100	32	1	27.2
" "	100	32	3,000	60.3

A process for the manufacture of alcohols and esters from olefins has been described by Buc.[77] The hydrocarbon is first esterified with a relatively high-boiling halogen-substituted fatty acid, using an aqueous sulphuric acid catalyst. The product is separated from the acid catalyst and either hydrolyzed to the alcohol or converted into the ester of an unsubstituted fatty acid. For instance, more than 80 per cent of the olefin was converted into the monochloroacetic ester by agitating at 45°C. for 12 hours a mixture of 250 cc. of a hexene (obtained by dehydration of hexanol-2), 400 cc. of benzol (as diluent), 100 g. of monochloroacetic acid and 140 cc. of 80 per cent sulphuric acid. The acid catalyst was added slowly during the reaction period. The product can be separated from the acid catalyst and hydrolyzed to furnish hexyl alcohol.

EFFECT OF PRESSURE ON DIRECT ESTERIFICATION

In the direct esterification of the *n*-butenes and *n*-pentenes with organic acids, such as anhydrous acetic acid, it is necessary to heat the reaction mixture under pressure to obtain satisfactory yields. Brooks[78] reports that heating butene-2 under pressure to 115-120°C. with an excess ot glacial acetic acid containing 10 per cent sulphuric acid gives rise to secondary butyl acetate in yields up to 60 per cent of the theoretical. Before treating cracked hydrocarbon distillates for the production of *sec.*-butyl and amyl acetates by this procedure, Brooks[79] first selectively removes tertiary olefins and diolefins present.

[78] **B. T. Brooks,** ***Ind. Eng. Chem.***, **1935, 27, 278.**

One continuous esterification process comprises contacting an olefin-bearing material in the gaseous state with a countercurrent liquid stream of an anhydrous organic acid containing an esterifying catalyst. The operating temperature is kept above 50°C. but sufficiently low to permit removal of the ester in liquid form.[80] For example, *n*-butenes were treated with glacial acetic acid and sulphuric acid in the relative proportions (by volume) of 1.67, 1.0 and 0.25, respectively, for 3½ hours at 75°C. and under a pressure of 10 atmospheres. Butyl acetate was obtained in a 52 per cent yield (based on the acetic acid) and tar formation amounted to only 3 per cent.

If boron fluoride is utilized as the motivating agent, esters may be formed under normal temperature and pressure conditions.[81] Aliphatic, aromatic or cyclic acids may be esterified in this way, as well as acid mixtures obtained by oxidation of paraffin wax or liquid petroleum distillates. Gaseous or liquid olefins are adapted to the above combination, which may be represented by the following equation. R,R′ or R″ may be a hydrogen atom or a substituted group.

$$R'{-}CH{=}CH{-}R'' + RCOOH \longrightarrow R'{-}CHOOCR{-}CH_2{-}R''$$

One method of carrying out the process consists in preparing a solution of boron fluoride in the oxygenated organic compound and agitating the mixture by means of the olefin reactant. The secondary olefins[82] have been found especially susceptible for such direct esterifications. The unsaturation point may occur in a ring or cyclic compound, such as cyclohexene, as well as in straight chain aliphatic hydrocarbons. For example, 20 parts of pentene-2 were treated at room temperature with 10 parts of an acetic acid solution of boron fluoride. Hydrolysis of the product gave a yield of 10.5 parts of secondary amyl acetate. In another instance, 19 parts by weight of boron fluoride dissolved in 30 parts of acetic acid gave 36 parts by volume of solution. On reaction of the mixture with 100 parts by volume of pentene-2, the resultant liquor occupied a space of 124 parts. From the latter, 39 parts by volume of secondary amyl acetate were recovered. More dilute sulphuric acid is used for the higher olefins, such as amylene and hexene, and more concentrated acid for the lower olefins, such as propene. The pressure employed is somewhat lower than the vapor pressure of the particular hydrocarbon under treatment. The flow of material is regulated so that the time of contact is between 2 and 4 hours. Yields of almost 100 per cent ester based on the fatty acid may be obtained.

The ester is recovered from the reaction liquor by extraction, the solvent best adapted for the purpose being a low-boiling gasoline or pure hydrocarbon such as pentane or hexane. The sulphuric acid and solvent can then be returned, separately, to the system for re-use.

Isham[83] suggests that the olefin be reacted with a sulphonic acid, e.g., benzene or naphthalene sulphonic acid, and the resulting alkyl sulphonate then be converted into the ester by heating with a carboxylic acid. An alternate procedure comprises subjecting the olefin to the simultaneous action of sulphonic and carboxylic acids. Another method involves heating a dialkyl sulphate with calcium salts of organic acids in the presence of diluents. The latter may be either carbon tetrachloride[84] or a kerosene fraction containing substantially saturated hydrocarbons.[85]

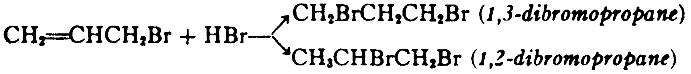
THE "PEROXIDE EFFECT" IN HYDROHALOGEN-OLEFIN ADDITION REACTIONS

In trying to establish the so-called relative electronegativity of various organic radicals, and in an extended study of the nature of the ethylene bond, some discrepancies between effects predicted by theory and those experimentally recorded led Kharasch and his co-workers to repeat the work on the combination of hydrogen bromide with allyl bromide and numerous other unsaturated compounds. Results obtained in these experiments seemed to indicate a definite effect of peroxides (or oxygen) on the direction of addition of halohydrogens to double-bonded hydrocarbons.

Allyl bromide reacts with hydrogen bromide in two different ways, namely,



$$CH_2{=}CHCH_2Br + HBr \begin{cases} \rightarrow CH_2BrCH_2CH_2Br \ (\textit{1,3-dibromopropane}) \\ \rightarrow CH_3CHBrCH_2Br \ (\textit{1,2-dibromopropane}) \end{cases}$$

An examination of this reaction, in the liquid phase and usually at room temperature, was carried out by Kharasch and Mayo.[86] They showed that although combination was very slow in the complete absence of oxygen or peroxides as well as in the presence of antioxidants,[87] the main product was 1,2-dibromopropane. With small amounts of oxygen or peroxides, a rapid reaction occurred with the almost exclusive formation of 1,3-dibromopropane. Factors such as presence of metallic salts as catalysts, use of various organic solvents and different temperatures or exposure to light all markedly affected the velocity of reaction but did not appear to exert any directive influence on it. The composition of the products was reported to depend entirely on the presence, or absence, of oxygen or peroxides. Similar conclusions were also reached in studies of the addition of hydrogen bromide to vinyl bromide[88] and to vinyl chloride.[89] In both cases, peroxides promoted formation of the 1,2-dihalogenated ethanes. On the other hand 100 per cent yields of the ethylidene (or 1,1-dihalogenated) compounds were obtained only in the absence of oxygen or peroxides as participants in the reaction.

Union of hydrogen bromide and allyl bromide in the presence of solvents and air was reported by Urushibara and Takebayashi[89a] to give 93 per cent of the 1,3-dibromo compound and 7 per cent of the 1,2-dibromo derivative. Some results obtained by these investigators with other catalysts are given in Table 69A. When reaction was effected in the absence of solvents, light and air, but employing reduced iron as the contact agent, yields of about 33 to 39 per cent of a mixture of dibromides were secured. Of the latter, 22 to 32 per cent was 1,2-dibromoallyl,

[87] In this work the investigators were unable to observe any difference in results between the behavior of a reaction mixture freed beforehand from peroxides and run in vacuo, and that of one run in vacuo or in air in the presence of a good antioxidant. The use of the term "with antioxidant conditions" applies to a known absence of oxygen or peroxide (*per se* or in effect) from the active reagents, whether obtained by previous treatment or by addition to the reacting mixtures. Of the large number of antioxidants tested those mentioned in the cases described were found most applicable with the reagents under discussion.

TABLE 69A.—*Proportion of Dibromo Derivatives from Allyl Bromide and Hydrogen Bromide.*

Catalyst	1,3-Dibromo Derivative, %	1,2-Dibromo Derivative, %
None	7	93
Air	93	7
Sulphur	17	83
Nitric oxide	12	88
Reduced iron	71	29
Reduced nickel	68	32
Platinum black	12	88
Ferrous bromide (anhydrous)	7	93
Manganese sulphate (anhydrous)	7	93

and 68 to 78 per cent the 1,3-dibromide.[89b] Substitution of reduced nickel for iron likewise resulted in a preponderance of the 1,3-dibromide being formed. On the other hand nickel (exposed to air for 5 weeks) or cobalt (freshly reduced or not) favored development of the normal product, i.e., 1,2-dibromoallyl.

Kharasch, McNab and Mayo[90] also studied the directive influence of peroxides on the union of liquid propene and liquid hydrogen bromide. When benzoyl peroxide or ascaridole[91] was added, *n*-propyl bromide was secured almost quantitatively.[92] The addition of antioxidants, e.g., diphenylamine or *ter*.-butyl isocyanide, to the reactants gave rise to pure isopropyl bromide.[93] The latter compound was procured also when reaction was carried out in an atmosphere of air.

These results were confirmed by the work of Brouwer and Wibaut[94] who found that oxygen had no influence on the course of the vapor-phase combination of propene with hydrogen bromide. Using silica gel as catalyst, the addition reaction proceeded smoothly at room temperature, furnishing about 90 per cent of isopropyl bromide, a certain amount of a by-product (probably hexyl bromide) and only a little *n*-propyl bromide. Contact agents prepared by impregnating silica gel with the bromides of zinc, ferric iron, aluminum or bismuth were of less utility than the pure gel. The absence of substantial proportions of *n*-propyl bromide in the products of vapor-phase operations, even in the presence of oxygen, may be due to the non-formation of peroxides, as suggested by Kharasch. According to Brouwer and Wibaut, both isopropyl bromide and *n*-propyl bromide undergo partial isomerization when heated to 250-275°C. in sealed tubes. The equilibrium mixture obtained after 100 hours at 250°C. consisted of 70 per cent isopropyl bromide and 30 per cent *n*-propyl bromide. After 36 hours heating at 275°C. an equilibrium mixture contained 67 per cent iso- and 33 per cent *n*-propyl bromide.

It has been shown by Kharasch and Hannum[95] that at room temperature propene combines vigorously with hydrogen iodide in the liquid state to yield iso-

propyl iodide exclusively. Peroxides did not change the course of the reaction and had no apparent influence on the time factor. It was suggested that the absence of the typical peroxide effect was due to rapid reduction and destruction of the peroxides by the halogen hydride. Similar observations were made in the case of butene-1 and neopentylethylene. With hydrogen iodide and allyl bromide, peroxides were found to exert a definite effect on reaction velocity and substantial conversions (68-81 per cent) of the olefin bromide into 1-bromo-2-iodopropane were obtainable only by their use.

Kharasch and his co-workers extended their study of the peroxide effect to the addition of hydrogen bromide to higher olefins. Thus, butene-1 furnished *sec.*-butyl bromide (2-bromobutane) quantitatively under antioxidant conditions. On the other hand, *n*-butyl bromide (1-bromobutane) was also formed in the presence of fairly large proportions of peroxides.[96] Since this reaction was not very sensitive to traces of peroxides, it was little influenced by external factors, such as solvents, temperature and light, which were found to affect only peroxide-catalyzed reactions of this type.

Union of hydrogen bromide and isobutene in the liquid phase has been investigated by Kharasch and Hinckley.[97] This reaction, which is rapid at room temperature, produces *ter*-butyl bromide exclusively under normal conditions, i.e., in the absence of peroxides. Other factors, such as temperature, light or solvents (glacial acetic acid and xylene) had little directive influence. However, with peroxides at least 80 per cent of the main reaction product was isobutyl bromide, $(CH_3)_2CHCH_2Br$. Since isobutene does not form peroxides readily, the latter bromide developed only in presence of added peroxides. Further work by Kharasch and Potts[98] indicated that under rigidly controlled antioxidant conditions, solvents (*e.g.*, pentane, carbon disulphide, ethyl bromide and nitrobenzene) have no directive influence on this addition although they markedly affect its velocity. In the presence of peroxides such as ascaridole, isobutyl bromide constituted 75-100 per cent of the total yield in the case of each solvent studied. Furthermore, Kharasch and Potts interpreted their results as showing that the apparent directive solvent effect noticed under other than antioxidant conditions was, in reality, an effect of the solvent upon the relative rates of the normal and the peroxide-catalyzed addition reactions.

By saturating pentene-1 or heptene-1, in organic solvents such as hexane, glacial acetic acid or carbon tetrachloride, with dry hydrogen bromide at atmospheric pressure and about 0°C., Sherrill, Mayer and Walter[99] found that the 1-bromo derivatives were formed exclusively. Prior to reaction the olefins gave no tests for peroxides. On the other hand, the addition products resulting from these olefins and aqueous hydrobromic acid (very slow reaction) at room temperatures during about two months, were exclusively the 2-bromo compounds. Accordingly, differences in the products by the two methods were attributed primarily to difference in solvents and not to presence of peroxides in the olefin. This conclusion has been contested by Kharasch, Hinckley and Gladstone.[100] They report that, under antioxidant conditions, pentene-2 combines with hydrogen bromide, either alone or in presence of glacial acetic acid, to yield at least 84 per cent

of 2-bromopentane. Also, in the presence of ascaridole and no solvents, 1-bromopentane is formed. According to Lauer and Stodola,[101] a mixture of 2- and 3-bromopentanes in about equal proportions is formed by interaction of pentene-2 with hydrogen bromide with or without glacial acetic acid as a solvent.

Brooks[102] compared the addition products of sulphuric acid and olefins of the type $RCH = CH_2$ with those obtained from the halogen acids and the same hydrocarbons. Treating pentene-1 with 85 per cent sulphuric acid differed from the addition of hydrogen bromide in yielding no primary derivatives for pentanol-2 was formed exclusively. The addition of hydrogen peroxide and finely powdered dibenzoyl peroxide to the reactants resulted in a product entirely free of any *n*-pentanol-1. The addition of sulphuric acid to pentene-2 gave a mixture of 65 per cent pentanol-2 and 35 per cent pentanol-3.

By passage of gaseous hydrogen bromide into 4,4-dimethylpentene-1 (at 0°C.), Whitmore and Homeyer[103] obtained only 1-bromo-4,4-dimethylpentene-1. They attributed this unusual mode of addition to the influence of the neopentyl group. However, Kharasch, Hannum and Gladstone[104] report that the 1-bromo-compound is formed only in the presence of peroxides (e.g., ascaridole). The "normal" addition compound, 2-bromo-4,4-dimethylpentane, is produced to a considerable extent in the presence of antioxidants (such as diphenylamine) in vacuo.

It is interesting to note that allyl acetic acid and hydrogen bromide, in hexane, formed only δ-bromovaleric acid ($CH_2BrCH_2CH_2CH_2COOH$) and the reaction was not reversed in the presence of hydrogen, diphenylamine or hydroquinone.[105] In the absence of a solvent either a freshly prepared sample of the unsaturated acid or one that gave a peroxide test yielded only γ-bromovaleric acid ($CH_3CHBrCH_2CH_2COOH$). However, when the diluent was not present, reversal of reaction (i.e., formation of δ-bromo acid) could be induced by the addition of dibenzoyl peroxide. Ashton and Smith[106] report that undecenoic acid either alone or in a solvent, in the absence of air, furnished only the 10-bromo acid. However, air or peroxides (for example, perbenzoic acid) gave rise to 11-bromoundecenoic acid. Ethyl undecenoate behaved similarly.[107] Isoundecenoic acid, however, always furnished a mixture of bromo acids (about 43 per cent of the 10-bromo compound) whether oxidants or antioxidants were present.[108] This probably indicated that only terminal double bonds were susceptible to the peroxide effect.

Treatment of styrene, dissolved in ethylbenzene, at 125°C. with hydrogen bromide is said to yield 63 per cent of α-bromoethylbenzene and 30 per cent of the β-bromo compounds.[109] If the temperature be reduced to 95°C. and benzoyl peroxide be added to the reaction mixture, then the yield of β-bromoethylbenzene is increased to 92 per cent.

Chapter 13

Production of Ethyl Alcohol from Ethylene

The increasing use of ethyl alcohol as a motor fuel, as a solvent and as a chemical intermediate acts as an impetus for research on all phases of its production. Until the last few decades this important substance was manufactured on a large scale by the controlled fermentation of grains, molasses, potatoes and cellulose. However, over a long period of years efforts[1] have been made to synthesize ethanol from ethylene present in coke oven gas,[2] oil gas, coal gas or cracking gas. Other promising sources of materials which have been investigated are hydrocarbons[3] obtained by catalytic conversion of the carbon monoxide in illuminating gas or water gas, and that made available on oxidation of lean fuels or the gas from oxygen generators. According to information available, only two companies[4] have successfully commercialized the manufacture of alcohol from any of these last mentioned carbonaceous products.

Nevertheless, in spite of the prevailing low prices of the naturally occurring raw materials for fermentation, it was officially reported[5] that over 14,000,000 proof, or 7,000,000 wine, gallons of synthetic alcohol were produced from ethylene in the United States during the year ending June 30, 1932.

Since large quantities of olefins are available in the cracking gases of the petroleum industry many procedures have been investigated which have as their object the direct addition of water to the ethylene[5a] molecule according to the equation:

$$C_2H_4 + H_2O = C_2H_5OH$$

A review of recent researches on the utilization of the above reaction has already been summarized (Chapter 11). The present chapter is concerned only with the indirect hydration of ethylene by absorption in sulphuric acid and subsequent hydrolysis of the acid liquor. Commercially, this process for ethanol synthesis has given results of increasing promise. The reactions on which it is based are well-known and may be written as follows:

$$C_2H_4 + H_2SO_4 \longrightarrow C_2H_5SO_4H$$
$$C_2H_5SO_4H + H_2O \longrightarrow C_2H_5OH + H_2SO_4$$

EARLY WORK ON INDIRECT HYDRATION REACTIONS

Although the fact that ethylene can be absorbed in large quantities by concentrated sulphuric acid was undoubtedly first observed by Faraday,[6] it remained for Hennell,[7] working in the former's laboratory, to note the possibility of forming

> "either alcohol or ether, using olefiant gas as the hydrocarbon base: for I have shown in my last paper[8] that olefiant gas by combining with sulphuric acid forms sulphovinic acid, and the acid so produced forms ether or alcohol, according to circumstances which are under perfect command."

Berthelot has often been given full credit by many writers for this discovery. On the other hand, Meldola[9] (in 1895) gave Hennell full credit and ranked his discovery on a par with the synthesis of urea by Wöhler at about the same time (1828).

Herstein[10] has recently summarized the actual accomplishments of the two workers as follows:

"Hennell clearly indicated the possibility of preparing ethyl alcohol from ethylene by hydration via ethyl sulphuric acid and supported it by partial proof: the credit for complete proof and the extension of this reaction to olefins generally belongs to Berthelot."

There was no important industrial development of any method based on the reactions made known by Hennell and Berthelot until about a decade ago, and only in the last few years has there been any substantial progress in its commercial application.

CONTROLLING FACTORS IN ACID ABSORPTION PROCESS

From the economic viewpoint, the great disadvantage of the sulphuric acid absorption process is that relatively large amounts of diluted acid must be continually reconcentrated. This difficulty, of course, disappears if there is a market for the dilute product, for example, in the form of ammonium sulphate. In most cases, however, the problem must be handled in some other way. Hence the industrial success of the absorption process is entirely dependent upon the amount of alcohol which can be produced in one treatment from a given quantity of acid.

According to Brooks,[11] two chief factors have changed the commercial aspect of ethylene as a source of synthetic ethyl alcohol, viz.,

1. The development of simple methods for separating the higher olefins from the ethylene-containing gases;
2. Reduction in the acid requirement by application of elevated pressures for increasing the absorption of ethylene.

Production of ethyl alcohol from ethylene by this method involves essentially three separate stages of operation;

1. Absorption of ethylene in concentrated acid;
2. Dilution, hydrolysis and distillation of the ethyl alcohol formed;
3. Reconcentration of the dilute acid.

Discussion of the final stage of the process would be out of place in this book.

ABSORPTION OF ETHYLENE IN CONCENTRATED SULPHURIC ACID

The products of the absorption of ethylene in concentrated sulphuric acid consist of ethylsulphuric acid, $C_2H_5HSO_4$, and the neutral ester, diethyl sulphate, $(C_2H_5)_2SO_4$, as well as of small amounts of polymeric hydrocarbons.[12] The ease of absorption depends primarily on acid concentration, temperature, partial pressure of the ethylene; secondarily on the type catalysts used, if any, and on the apparatus employed in contacting the gas with the acid absorbent.

Concentration of Acid. As already pointed out, 98 per cent sulphuric acid appears to be most applicable for good yields of alcohol. Acid in 100 per cent concentration, besides being probably too costly, causes carbonization and renders temperature control difficult. Fuming sulphuric acid converts ethylene first into ethionic acid and then into carbyl sulphate.[13] The latter substance is formed exclusively by the action of gaseous sulphur trioxide on the olefin. Neither of these products is of value in the manufacture of ethyl alcohol.

The absorptive power of aqueous sulphuric acid towards ethylene rapidly diminishes with decreasing acid concentration even under high ethylene partial pressures. This is readily seen from Brooks' data which is discussed in Chapter 12.

Temperature. The absorption rate is increased by operating at temperatures up to about 75-80°C., above which side reactions such as decomposition, carbonization and formation of sulphur dioxide tend to become troublesome.

Pressure Effect. The use of high partial pressures of ethylene greatly increases both the speed of absorption and the quantity of the unsaturated hydrocarbon reacting with a given amount of sulphuric acid. In this connection, the results of experiments recorded by Brooks[14] are of interest. He points out that reduction in pressure from 500 to 200 lbs. per sq. in. is accompanied by a decrease in absorption from 1.25 to 0.6 moles of olefin per mole of acid.

By contacting ethylene with concentrated sulphuric acid (d 1.845) at 80°C. in a mixer rotated at 600-1000 r.p.m., Dalin and Gutuirya[15] obtained 1 kg. of ethyl alcohol per 3.2 kg. of sulphuric acid when working at atmospheric pressure. The acid consumption was reduced to 2.4 kg. per kg. of alcohol at 15 atmospheres pressure.

Strahler and Hachtel[16] investigated the absorption of ethylene in concentrated sulphuric acid at pressures up to 15 atmospheres. Their apparatus was an electrically-heated autoclave of V2A steel, fitted with a stirrer. The amount of sulphuric acid required to produce 1 kg. of ethanol was reduced from 5 kg. to 2 kg. by increasing the pressure from 1 up to 15 atmospheres. At 70°C., 15 atmospheres and a gas flow of 4 liters per hour per mole of acid, 400 g. of olefin had been absorbed per kg. of sulphuric acid (66°Bé.) after 24 hours. Of the original gas, 25 per cent was converted into diethyl sulphate, 3 to 5 per cent into polymers and the remainder into ethylsulphuric acid. Total absorption was not increased after the 24-hour period and was greatly reduced (under similar conditions) by the use of less concentrated acid.

Nevertheless it has been proposed[17] to absorb ethylene, under pressures up to 250 atmospheres, in 60 to 75 per cent sulphuric acid at 90-150°C. The product is said to consist of a mixture of alcohol and ether, the proportion of the latter increasing with rising temperature of reaction. At 47 atmospheres pressure and 90°C., in 75 per cent acid, operation for 4 hours followed by hydrolysis and distillation furnished 119 g. of alcohol per kg. of sulphuric acid and practically no ether. At 140 atmospheres the yield was 166 g. of alcohol per kg. of acid. Brooks[18] proposes to synthesize ethyl alcohol from the mixture of ethylene and saturated hydrocarbons left after removal of higher olefins from cracking gases. The olefin-bearing residue, under pressures of 300-550 lbs. per sq. in., is contacted with 90-100 per cent sulphuric acid at 70-100°C. The resulting acid liquor is then hydrolyzed.

CATALYSTS FOR THE ABSORPTION REACTION

It has been recognized for some time that the absorption of ethylene in strong sulphuric acid is quickened by certain activators.[19] Actually the reaction is autocatalytic, being accelerated by ethylsulphuric acid itself.

Brooks and Schuler[20] report that the presence of about 10 per cent ether not only inhibits ether formation when the sulphuric ester is hydrolyzed to alcohol but actually promotes ester formation. In their experiments the acid was of 50-100 per cent concentration, and combination with ethylene was effected at 70-100°C. It was observed that less water was needed for the subsequent hydrolysis than was usually the case. On the other hand, Bailey and Calcutt[21] point out that when diethyl ether or nitrobenzene is dissolved in sulphuric acid not only is the surface tension of the latter lowered but also the solute molecules appear to be concentrated at the surface of the solution and thus decrease the rate of absorption of the olefin. In the case of the ether, each molecule concentrated in the surface layer seemed to prevent about 4 to 5 molecules of acid from reacting. The inhibitory action of nitrobenzene was attributed to its power of decomposing the ethylene-sulphuric acid complex, $C_2H_4 \cdot H_2SO_4$, which represented the first step in the absorption phenomenon. Both inhibitors were much less effective when the acid layer was agitated than when it was static.

Effect of Metallic Catalysts. Silver sulphate and cuprous chloride have been found by Strahler and Hachtel[22] to increase the initial rate of absorption when operating under 15 atmospheres pressure. However, the rate subsequently decreased and the total absorption was the same as that obtained in the absence of these metallic salts. In general, contact agents appear of doubtful value in large-scale operation. They tend to promote polymer formation, and rapid reaction can be attained by operating without them under pressure at about 80°C.

A systematic examination of a number of catalysts has been carried out by

[22] F. Strahler and F. Hachtel, *loc. cit.*

Gutuirya and Dalin.[23] They found that of a large variety of materials, only iron and silver were useful in the commercial production of alcohol. Some of the more active substances, such as cuprous chloride, seemed to lower the alcohol yield on prolonged contact. It was observed that satisfactory results could be obtained with iron at 65-70°C. This fact permits use of an iron contact apparatus, in the presence of which the metallic content of the acid increases by only about 0.3 to 0.4 per cent in 24 to 30 hours.

In this connection, Pigulevskii[24] reports that the absorption of propene in sulphuric acid, although autocatalytic, is markedly less accelerated by the presence of silver salts than is the case with similar treatment of ethylene or any of the butenes. According to Dalin and Gutuirya,[25] fused silica in small pieces is helpful when cracking gas is employed as the source of olefins.

Catalysts suggested by van Peski[26] include complex metallic cyano compounds. For the absorption of ethylene alone in about 96 per cent sulphuric acid, this investigator[27] mentions the use of compounds of copper, iron, cobalt or nickel (excluding complex organic compounds), as well as metals of the platinum group. The suggested catalysts included such substances as cuprous cyanide, cuprous oxide and cupric chloride as well as soluble complex compounds obtained by the action of carbon monoxide, or nitric oxide,[28] on the metal salts in acid solution, such as $Cu_2SO_4(CO)_x$ and $Cu_2SO_4(NO)_x$.

Organic Catalysts. For the manufacture of ethyl alcohol and ethyl ether from ethylene, Dreyfus[29] proposes to absorb this olefin in sulphuric or phosphoric acid containing water and at least 5 per cent of an ester of the inorganic acid. For example, ethylene is treated at 79°C. and 2 atmospheres pressure with 90 per cent sulphuric acid containing 5 per cent of glycol monosulphuric ester and 10 per cent of sulphoricinoleic acid. After hydrolysis the ethanol is recovered by distillation. The use of acids weaker than sulphuric, e.g., 40-80 per cent phosphoric or organic sulphonic acids, and high pressures (30-200 atmospheres) and temperatures (150-300°C.) has also been proposed by Dreyfus.[30] Catalysts may be present, such as silver, silver sulphate, cuprous oxide, as well as calcium, lead or ferrous sulphate.

TREATMENT OF GASES PRIOR TO ABSORPTION

Given a mixture of olefins, it is the usual practice to remove propene and its homologs by preferential absorption in more dilute sulphuric acid, prior to interaction of ethylene with more concentrated sulphuric acid. Dreyfus and Groombridge,[31] however, propose to extract propene from gas mixtures of this type by utilizing 80-90 per cent acid at 20-23°C. Ethylene in the residual gas is then treated with acid of lower concentration (75-85 per cent) at a higher temperature: in this case, 90 to 130°C.

The necessity of eliminating higher olefins from the ethylene fraction of cracking gas is pointed out by Gutuirya, Dalin and Shenderova.[31a] They find, when absorption of ethylene is carried out at atmospheric pressure, that an increase in the propene content (of the ethylene fraction) decreased the yield of ethanol by 29 per cent. Simultaneously the proportions of polymers and isopropyl alcohol formed rose to 8 and 35 per cent, respectively. At higher pressures (10 to 12 atmospheres) an increase in the propene content of the gases from 1 to 2 per cent resulted in a 22.5 per cent yield of polymers and 5.6 per cent of isopropanol.

Fussteig[32] reports tests made on removing ethylene from cracking gases. The use of sulphuric acid of increasing strength and a copper-silver-chloride catalyst was abandoned due to lack of contact between gas and acid as well as formation of mercaptans from the butadiene in the raw material. Selective adsorption by active carbon was adopted as most satisfactory. Dried gases from vapor-phase cracking had all olefins but ethylene extracted by activated charcoal at 40°C. Sulphuric acid of 66°Bé. concentration served to absorb the ethylene, from which alcohol could be obtained by the usual methods.

Contacting Apparatus

The rate of reaction between ethylene and sulphuric acid under any definite set of circumstances apparently depends markedly upon the type of apparatus employed. Conditions favoring the most intimate contact of gas with acid liquor give the best results. Countercurrent passage of gas and acid liquor in specially constructed towers is often employed, although mechanical agitation is likewise practiced. Dalin and Gutuirya[33] have reported efficient conversion in a mixer equipped with paddles and perforated discs and rotated at 600 r.p.m. Lower or higher speeds of the rotor resulted in lower absorption rates.

For ethylating sulphuric acid with a gas containing initially about 30 per cent ethylene and 70 per cent inert material, Stuart[34] employs a system of three towers in which the gas is scrubbed with the acid. The feed gas is passed in parallel through two of these towers containing acid of which the degree of ethylation increases (per mole of SO_3 present in any form) from 0 to 0.4 mole and from 0.9 to 1.3 mole, respectively. The exit gases from these columns are then passed through a third tower where ethylation of the acid increases from 0.4 to 0.9 mole of ethylene (per mole of SO_3). As soon as the upper limits of ethylation are attained, the path of the gas is rearranged after fresh acid has been substituted for the fully saturated liquor. This latter contains up to 1.25 mole of ethylene per mole of sulphur trioxide present as sulphuric acid, ethyl sulphuric acid and diethyl sulphate. The proportions of the final constituents may vary within wide limits. The process is intended for the selective extraction of one gas from a mixture of gases. The procedure described was planned to afford an exceptionally efficient scrubbing action just prior to the exit of the mixture from the system.

Kramer[35] describes an apparatus in which olefins of the type $R_2C = CHR$, dissolved in a mineral oil, are contacted in countercurrent with the absorbing acid (sulphuric) in a series of alternate agitating and settling chambers. Contiguous chambers only are connected. Hydrostatic heads of acid and olefin-bearing oil in the settling zones are in the same ratio as the amounts of these two liquid phases in the agitating zones. The treated material is removed from the apparatus at a settling compartment. Sulphation of olefins may also be effected, according to this same investigator,[36] in the presence of a circulating liquid medium of large heat capacity. Precooling below the maximum reaction temperature avoids exceeding the temperature at which the product desired is stable. The circulating fluid may be an inert liquid or one of the reactants, or an easily separable secondary reaction product.

HYDROLYSIS OF ETHYLATED SULPHURIC ACID LIQUORS

The alkyl hydrogen sulphates, although fairly stable in the presence of water at ordinary temperatures, are rapidly hydrolyzed on heating. The rate of hydrolysis is greatly accelerated by hydrogen ions[37] and for this reason takes place readily in dilute acid solution. In alkaline solution the monoalkyl sulphates (or, rather, their alkali salts) are only very slowly hydrolyzed, even on boiling. In moderately concentrated sulphuric acid solutions, an equilibrium is set up between alkylsulphuric acid, water, free sulphuric acid and alcohol, according to the equation,

$$ROSO_3H + H_2O \rightleftharpoons ROH + H_2SO_4$$

Hydrolysis of Ethylsulphuric Acid. In the case of ethylsulphuric acid, substantial proportions of ethyl alcohol are present in the equilibrium mixture even with relatively concentrated sulphuric acid. However, the recovery of ethanol by heating the mixture is not feasible because dehydration to ethylene and also to ether tends to occur. In fact, the degree of dilution with water necessary in the industrial production of alcohols is largely controlled by the necessity of suppressing such undesirable or analogous side reactions. These secondary combinations are in general more pronounced with the higher olefins than with ethylene. In the case of ethyl or isopropyl hydrogen sulphates, hydrolysis and distillation may be carried out in solutions of 35 per cent sulphuric acid without appreciable breaking down of the alcohol molecule. With the higher monoalkyl sulphates, olefin formation, usually accompanied by polymerization, is always a controlling factor.[38]

Hydrolysis of Dialkyl Sulphates. The dialkyl sulphates are also hydrolyzed in the presence of hot water and the reaction is accelerated by hydrogen ions. In moderately concentrated sulphuric acid solution an equilibrium is set up as follows:

$$(RO)_2SO_2 + H_2O \rightleftharpoons ROSO_3H + ROH$$

However, the hydrolysis of the dialkyl sulphates is complicated by ether formation even in fairly dilute acid solutions, which does not happen in the case of the monoalkyl sulphates. Thus, while ethyl alcohol may be distilled without appreciable ether production from a 40 per cent sulphuric acid solution, the addition of diethyl sulphate to such a mixture causes as much as 30 per cent of this ester to be converted into ether, probably thus:

[38] B. T. Brooks, *Ind. Eng. Chem.*, 1935, **27**, 278; *Brit. Chem. Abs.* **B**, 1935, 536; *Chem. Abs.*, 1935, **29**, 2700.

$$(C_2H_5O)_2SO_2 + C_2H_5OH \longrightarrow (C_2H_5)_2O + C_2H_5O \cdot SO_3H$$

According to Brooks,[39] this reaction, discovered long since by Erlenmeyer,[40] is mainly, or wholly, responsible for the formation of ethyl ether in the customary method of preparation, viz., treatment of alcohol with sulphuric acid.

The formation of ethyl ether[41] in the hydrolysis of diethyl sulphate may be minimized by separating the ester from the acid reaction product, which may be hydrolyzed separately with water or dilute acid. An alternate method is to add the ester gradually to boiling water in which the alcohol concentration is kept low by continuous distillation.

For the hydrolysis of an acid liquor containing mainly ethylsulphuric acid and unchanged sulphuric acid, Dalin and Gutuirya[42] recommend dilution with 53 parts by weight of water for 47 parts of acid liquor, followed by distillation and rectification. The same investigators[43] have reported alcohol production by treatment of petroleum gases carrying 17-18 per cent ethylene. Absorption in a concentrated medium was carried out at 65-75°C. under 15-20 atmospheres pressure. The resulting liquor, after dilution with an equal weight of water, was heated to 160-170°C. in a tube still. The product collected was 92-94 per cent alcohol.

Groombridge and Peek[44] recover alcohol or ether from acid liquors by hydrolysis with an equal weight of water. The mixture passes down a copper column packed with pumice and indirectly heated to 125-130°C. at the base. Vapors of the product distil off from the top and the acid is said to be regenerated by the time it reaches the bottom of the tower. Stuart[45] recommends introducing the acid alkyl sulphate material in regulated proportions into a stream of water at intervals along the line of flow. The alcohol formed may be collected after distillation.

When ethylene has been absorbed in sulphuric acid and the mixture contains flocculent carbonaceous impurities, due to polymer formation, two methods of treatment are available:

1. The esters may be first hydrolyzed by dilution with not less than two volumes of water, and the dialkyl sulphate[46] extracted with a water-immiscible solvent, such as diethyl ether.

2. Dilution by not less than 4 volumes of ethyl alcohol or ether may precede filtration to remove precipitated impurities. The diethyl sulphate[47] is then separated after hydrolysis of the filtrate with water.

Another process[48] involves the use of 90-100 per cent sulphuric acid at 70-80°C. for the absorption of ethylene. Under these conditions, with 20 atmospheres pressure, a high percentage of diethyl sulphate is obtained. This ester may be separated by distillation above 130°C. at 20 mm. pressure. Hydrolysis with water and distillation produces ethyl alcohol. It is reported that no ether is formed in this procedure and that the dilute acid is free from carbon.

Dreyfus[49] recovers ethyl alcohol from diluted and hydrolyzed acid liquor by either of two methods:

1. Use of certain selective solvents, such as chlorobenzene, hydrogenated naphthalene or tetrachloroethane; or
2. Azeotropic distillation in the presence of an entraining agent such as benzene, chloroform, trichloroethylene, *n*-hexane or cyclohexane.

Sargent[50] recommends that an alkyl sulphate mixture, derived from olefins of less than 4 carbon atoms and carrying a considerable proportion of dialkyl sulphate be mixed with not more than an equal weight of water. After the resultant emulsion has been agitated at 70-80°C. for 20 minutes to 1 hour, alcohol and ether may be recovered by distillation. If this is continued until the density of the distillate is 0.999, the concentration of the sulphuric acid in the still should be about 67-72 per cent.

Hydrolysis of Diethyl Sulphate. Graham[51] effects hydrolysis of diethyl sulphate liquor by regulating its addition to boiling water so that the alcohol distils out of the water continuously as rapidly as the sulphate liquor is added. A larger yield of alcohol is thought to be possible in this way than by the usual methods. An analogous procedure has been described by Scott, Bovier and Matthews.[52] Wilson[53] removes acid from the zone of reaction by hydrolyzing alkylated liquors in the presence of bauxite, or with water alone, followed by neutralization of the free acid with bauxite. Alcohols and aluminum sulphate are produced.

The effect of strong acids on the alkyl sulphates is emphasized by the following reactions reported by Kohler.[54] The acid used in his experiments was hydrogen chloride in the gaseous form.

$$C_2H_5SO_4K + HCl = KHSO_4 + C_2H_5Cl$$
$$(C_2H_5SO_4)_2Ba + 2HCl = BaSO_4 + H_2SO_4 + 2C_2H_5Cl$$

The potassium acid sulphate formation was reported as proceeding quantitatively at 145°C. The barium salt was completely decomposed at 65 to 80°C.

The effect of moisture on diethyl sulphate, with consequent damage to containers used for storage, has been investigated by Siebeneicher.[55]

TECHNICAL PROCEDURES

According to Sidersky,[56] one widely discussed commercial plant[57] for the production of synthetic alcohol separates an ethylene-rich fraction from coal gas by fractional liquefaction and distillation. The olefin is absorbed under high pressure by a liquor composed of sulphuric and ethylsulphuric acids. The product is then said to be hydrolyzed by blowing steam through the acid medium. The yield of alcohol is reported as 6.5-10.8 liters per ton of coal.

[57] Reference is here made to the plant of the Compagnie de Bethune. A sample of their product was found to contain 0.05 per cent acetaldehyde, 0.3 per cent acetone, and 3.7 per cent isopropanol. After repeated fractional distillations 1 per cent of the latter was still present. The tests were made by J. Stastny and V. Vilikovsky (*Vestnik Ceskoslov. Akad. Zemidilske*, 1934, 10, 526; *Chem. Abs.*, 1936, **30**, 3402) who report convenient analytical procedures for the determination of acetone and isopropyl alcohol.

A semi-commercial plant in Russia has also been described.[58] In one semi-technical unit, the ethylene-containing material (cracking gas) was freed from high olefins by passage over active carbon. From the latter, the higher olefins could be expelled periodically by the use of superheated steam.[59]

DEHYDRATION OF ETHYL ALCOHOL

Fractional distillation of aqueous ethyl alcohol in the absence of entraining agents is not sufficient to yield anhydrous alcohol. A constant boiling mixture with water is always obtained, the composition of this azeotrope depending on the pressure at which fractionation is carried out. Under normal conditions, the azeotropic mixture contains 95.57 per cent by weight of ethyl alcohol and 4.43 per cent of water; it boils at 78.15°C. For many industrial purposes alcohol containing not more than about 0.2 per cent of water is required. Several processes are available for preparing this so-called "absolute alcohol" by dehydration of the alcohol-water azeotrope that results from simple fractionation. The familiar use of quick lime for this purpose has been supplanted by the more economical method of azeotropic distillation for which benzene and similar entraining liquids are applicable.[60]

Several azeotropic distillation methods are in commercial use and a large proportion of the total absolute alcohol produced is obtained in this manner. A mixture of benzene and a gasoline fraction is employed as dehydrating agent at atmospheric pressure in the Guinot[61] process. In another plant of the same type[62] dehydration is effected azeotropically by means of benzene under a working pressure of 10 atmospheres. In a third azeotropic dehydration system, known as the Drawinol process,[62a] stabilized[63] trichloroethylene functions as the entraining agent.[64]

In azeotropic dehydration of ethyl alcohol, since vapors from the rectification stage are used for heating the dehydration stage, Renotte[65] proposes to concentrate the alcohol in the former stage to a point considerably below 96° Gay Lussac.[66] Under these conditions the heat required for dehydration corresponds to that supplied by the alcohol vapors from the rectifiers. An economy of fuel is possible by this method of operation.

[66] According to Watt's Dictionary (1872), Gay Lussac's determinations of sp. gr. were made at 15°C. The 96° alcoholometer reading refers to 96 per cent alcohol by volume.

Absolute ethyl alcohol obtained commercially by azeotropic distillation is said[67] to have the following physical constants:

Density (25°C.)	0.78523
Boiling point	78.38°C.
Rate of change of b.p. with pressure..	0.034°C./mm.Hg.

Physical constants and analytical data on benzine, as used in Poland for dehydration of alcohol by azeotropic methods, have been made available by Sosnowski and Treszczanowicz.[68] Compositions and boiling points of the azeotropic, or benzine-alcohol, and of the heteroazeotropic or benzine-alcohol-water systems have been determined. The benzine consisted of 69 per cent heptane. In carrying out an azeotropic dehydration of ethyl alcohol, the boiling points of "heteroazeotrope" (64 vol. per cent benzine, 5 per cent water and 31 per cent alcohol) and "azeotrope" (52.6 per cent benzine and 47.4 per cent alcohol) were, on the average, 69.7°C. and 72.5°C., respectively.

It is to be noted that solid dehydrating agents appear to be coming into use again. In the Gyp process,[69] wet alcohol vapors are contacted in a countercurrent system with a stream of finely-divided anhydrous gypsum (dried at not less than 160-180°C.). The anhydrite is converted into a semi-hydrate and the alcohol produced is reported as about 99.8 per cent pure.[70] The used anhydrite is regenerated by air-drying at about 175°C. Steam consumption in this process is said to be only 40 kg. per hectoliter of alcohol. The process is carried out in a very small space and requires no columns and no liquid spirit is in circulation. The dehydrating material is very cheap and the losses of alcohol are less than 0.5 per cent. Conversion costs (in Cuba, 1934) for dehydrating from 94 per cent to 99.8 per cent product were calculated as one-half cent per gallon of alcohol.

A process that combines the use of solid or liquid absorbents with fractional distillation is described by Du Bois.[71] The method takes advantage of the fact that anhydrous alcohol can be obtained in a single operation by distillation of aqueous alcohol provided its concentration is above the azeotropic point (97.2 per cent). Thus, in practice, part of the high strength alcohol (98 per cent or over) is returned to the distillation tower so that the concentration of alcohol therein is above that of the azeotropic mixture. The vapors are then dehydrated with a solid absorbent in another vessel and again returned in part to the distilling column. Economical operation calls for maximum heat recovery. The final product is reported to be substantially free of water. It is further stated that this modified absorbent method can compete advantageously with azeotropic distillation.

In the Hiag process,[72] ascending wet alcohol vapors are sprayed with a solution, or suspension, of dehydrating salts (sodium acetate, alone or mixed with potassium acetate). The dried vapors, when condensed, furnish a 99.8 per cent alcohol. The aqueous-alcoholic solution of the salts is freed from alcohol in a small column. Water is removed from the hydrated salts in a regenerator by heating indirectly with superheated steam at 300°C. The dried salt is then passed into a vessel containing absolute alcohol and returned to the dehydrating tower for further use.

A process in which lime is employed under pressure as a drying agent[73] is also practiced commercially.[74] Kyrides[75] suggests the use of alkali alkoxides or phenoxides for the dehydration of aqueous alcohols. For example, absolute ethyl alcohol may be prepared by the action of disodium glycolate on a water-ethanol mixture.

ETHYL ALCOHOL AS A FUEL

The addition of certain proportions of ethyl alcohol to motor fuels has been made compulsory by law in many countries, nominally for the purpose of assisting agriculture and of furthering economic nationalism. The relative merits and demerits of this alcohol as a constituent of motor blends have been described in numerous trade journals as well as scientific reports. Only a relatively brief summary of the salient features of the problem is possible in a book of this character. Discussion of the voluminous literature on the use of ethanol in gasoline-alcohol mixtures will be found in Chapter 44.

Alcohol Fuels in Paste Form. A minor use of alcohol is in the form of so-called "gels" where heat production is required only for short periods. For this purpose Fleming[76] incorporates 3 parts of nitrocellulose (insoluble in alcohol) in a solution of 2 parts of an alcohol-soluble nitrocellulose in 95 parts of ethanol. Citric acid may be included (in small quantity) as an antigelating agent.

McBain[77] disperses 3 per cent of an insoluble (under normal conditions) nitrocellulose in ethyl alcohol at —30 to —60°C. The colloidal solution is then warmed to room temperature. The resultant gel may be used as "canned fuel."

An unusual, white, opaque, aqueous, alcoholic gel containing ethanol and having a tendency to crystallize has been prepared by Henstock.[78] This was done by adding the alcohol to an aqueous solution of potassium ethyl sulphate. The composition was represented by the formula,

$$KC_2H_5SO_4 \cdot 6H_2O \cdot 6C_2H_5OH$$

It persists for 48 hours at 15°C. but crystallizes rapidly at higher temperatures. Its precipitation from aqueous solutions by alcohol has been recommended as a means of identifying potassium ions.

ETHYL ALCOHOL AS A CHEMICAL INTERMEDIATE

Ethyl alcohol is extensively used as a raw material for the production of a wide variety of organic chemicals, including diethyl ether, ethyl esters, acetaldehyde, crotonaldehyde, normal butanol, acetic acid and acetic anhydride, as well as ethylated bases such as ethyl aniline.

ETHERS FROM ETHANOL

Diethyl ether is obtained in considerable quantities as a by-product when ethyl alcohol is made from ethylene by the sulphuric acid absorption method, as already noted.

A determination of the boiling point of specially purified diethyl ether has been made by the U. S. Bureau of Standards,[79] and found to be 34.481 ± 0.003°C. The *dt/dp* ratio for ether, in degrees per mm. at 760 mm. of mercury, is given as 0.0372.

This ether may be produced by the anhydration of ethyl alcohol by means of numerous catalysts. Yields up to 45 per cent were reported when ethanol was heated below 300°C. with anhydrous aluminum sulphate, alumina or thoria. It is also reported that the following materials[80] were effective catalysts: copper sulphate, tin chloride, manganous chloride, aluminum chloride, potash and chrome alum and chromium sulphate.

Similar procedures were followed by Brown and Odell[81] using alumina at pressures above atmospheric and heating the alcohol above its critical temperature. Another process[82] furnishes ethers and alcohols from olefins and liquid water by use of the same catalyst. Normal pressure is effective at temperatures above 100°C., but at 250 to 365°C. more than 10 atmospheres were necessary. In the latter case the higher temperature was reported for alcohol formation. Operation at 250°C. favored ether formation as did increasing the ratio of olefin to water.

It has been proposed[83] to carry out the production of ethers from alcohols in two successive stages. In the first, aqueous ethanol is passed (oxidizing gases being excluded) over alumina, iron oxide or chromium oxide at about 300°C. The olefin produced is at once converted into ether by passage over a second catalyst, used at 50-400°C., and composed of metallic salts, such as sulphates and chlorides, activated by a silver salt. Both conversions take place at normal pressure.

Kosolapov[84] studied the anhydration of alcohol with mixed catalysts prepared by ammoniacal precipitation of nitrates of alumina (with additions of iron, calcium or vanadium) followed by activation at 360°C. The pyrolytic reactions resulted in the formation of some methane and ethane as well as aldehydes, but no hydrogen, in gaseous mixture along with the normally produced ethylene. Kosolapov thinks breaking up of the alcohol molecule by catalysts may be as indicated by the following reactions:

$$\begin{aligned} 2C_2H_5OH - 2H_2O &\longrightarrow CH_3CH{=}CHCH_3 \longrightarrow 2C_2H_4 \\ 2C_2H_5OH - H_2O &\longrightarrow CH_3CHOHCH_2CH_3 \longrightarrow CH_3CHO + C_2H_6 \\ C_2H_5OH &\longrightarrow HCHO + CH_4 \end{aligned}$$

Adadurov and Krainii[85] made a similar study using, at 300 to 400°C., contact agents of alumina deposited in varying amounts on charcoal. The rate of ethylene formation at 350°C. was increased by eighteen times after an 8-fold increase in concentration of alumina. A similar multiplication by 45 occurred when pure catalyst without carrier was utilized.

The anhydration reaction may also be carried out in the presence of liquid acid catalysts such as sulphuric acid. According to Schumann and Ufer,[86] ether may be continuously distilled off while contacting a vaporous mixture of concentrated

aqueous alcohol with ethylsulphuric acid (and a small amount of sulphuric acid as catalyst) at a temperature above 100°C. (See Fig. 99.)

Alcohol from Ether. The transformation of ethyl alcohol into ether and water is, of course, a reversible reaction. Vansheidt and Lozovskii[87] found that diethyl ether could be hydrolyzed, after 2 to 4 hours' treatment, to the extent of 70 per cent by heating with 5-25 per cent aqueous sulphuric acid at 200°C. The yield of ethyl alcohol was considerably lessened by the use of more concentrated sulphuric acid or if the temperature was allowed to exceed 230°C. (Under similar conditions no hydrolysis resulted from use of phosphoric acid.)

FIG. 99.—Sketch of Method for Continuous Production of Ether from Ethylsulphuric Acid and Ethanol. (C. Schumann and H. Ufer)

Semerano[87a] investigated the equilibria of the reaction at temperatures of 249°

$$2C_2H_5OH \rightleftharpoons (C_2H_5)_2O + H_2O$$

and 266°C. and pressures of 10 to 70 atmospheres. A mixture of the oxide and phosphate of aluminum was employed as a catalyst. The use of high pressures made it possible to maintain the quantities of alcohol or ether which decomposed into ethylene and water within very narrow limits. It was found that the reaction was favored by increasing the temperature and decreasing the pressure. From calculations based on the equilibrium constants at atmospheric pressure it was concluded that at 249° and 266°C., approximately 85 per cent of the alcohol can be etherified.

An alumina catalyst prepared by neutralizing an aqueous alkaline solution of sodium aluminate with nitric acid was found by Kagan and his co-workers[88] to be much superior to alumina prepared by Willstätter's method as regards activity in promoting the hydration of diethyl ether. Passage of a mixture of ether with 2.5 parts of water vapor over this alumina catalyst at 325°C. furnished 22.5 per cent of ethyl alcohol, 6 per cent of ethylene, and a residue of unchanged ether.

Since the production of ethyl ether as a by-product has accompanied the development of synthetic methods for the manufacture of ethanol from olefins, it has become desirable to convert ether to alcohol. As has been noted above, this can be done by contacting the ether with mineral acids under certain conditions of temperature and pressure. Lewis[89] suggests use of pressure greater than 225 lb. per sq. in. and a temperature of about 270°C. in order to supply alcohol of high purity in good yields. As a catalyst, 10 per cent sulphuric acid is recommended. Other acids, e.g., hydrochloric (5 to 6 per cent), and phosphoric (15 to 20 per cent), or salts such as chlorides of aluminum or zinc (which are acidic in dilute aqueous solutions), may function as contact materials. Two or more catalysts may be present and promoters may be added, such as metallic silver or oily substances (mineral or fatty oils or Turkey-red oil).

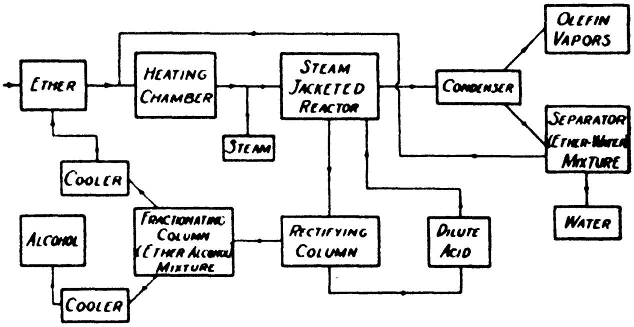

FIG. 100.—Flow Diagram for Conversion of Ethers to Alcohols. (W. K. Lewis)

The best operating temperature is between 240 and 260°C. since higher temperatures result in formation of olefin instead of alcohol.

A major requirement of the process is the application of sufficient pressure to prevent evaporation of water from the aqueous catalyst. The lower limit seemed to be about 225 lbs. per sq. in. at 200°C., but from 500 to over 1000 lbs. per sq. in. may be used. With a fairly high pressure, the alcohol may be retained in the liquid phase and recovered from the dilute liquid catalyst by distillation, after reduction of pressure. For example, at 250°C. with a pressure of 2000 lbs. per sq. in., using a 10 per cent sulphuric acid catalyst, the acid liquor withdrawn contained 20 to 22 per cent alcohol and practically no alcohol was found in the vapor discharged at the time.

In another instance, ether was vaporized and passed into a reaction vessel containing 10 per cent sulphuric acid heated to a temperature of 272°C. Ether vapor was then continuously supplied to maintain a pressure of 2000 lbs. per sq. in.

[89] W. K Lewis, U. S. P. 2 045 785, June 30, 1936, to Standard Oil Development Co.; *Chem. Abs.*, 1936, **30**, 5589. British P. 456,547, 1936; *Brit. Chem. Abs.* **B**, 1937, 31; *Chem. Abs.*, 1937, **31**, 2229.

during a contact period of 25 minutes. The acid liquor withdrawn at the end of this time contained 22 per cent ethyl alcohol. The latter was recovered from the acid by distillation at normal pressure and represented a conversion of over 90 per cent of the ether fed into the system. On increasing the time of reaction to 100 minutes, alcohol concentration fell to 16 per cent and an equivalent amount of ethylene was found in the exit gases. It was shown that the time of contact required for reaction could be greatly reduced by increasing the agitation or degree of contact between the acid and the ethers. See Fig. 100.

On the other hand, high pressures (1000-5000 lbs. per sq. in.) and a temperature of 250-350°C. have been proposed[90] for the conversion of ethanol into diethyl ether.[91] A non-oxidizing inorganic acid, e.g., phosphoric acid, is added to the alcohol which circulates in a flow system, both alcohol and acid being maintained in the liquid phase.

A number of other catalysts for the hydrolysis of diethyl ether to ethanol have been investigated.[92] In each instance, vapors of ether and water were generated separately and then passed jointly over the contact agents at 280-350°C. Ferric oxide was not effective, but oxides of zinc, magnesium and aluminum were increasingly active in the order named. Mixtures of oxides were even better, those of aluminum and iron being most efficient and those of aluminum and magnesium and of aluminum and zinc being less so. In the absence of water, ether decomposed to ethylene, aluminum oxide being the most active catalyst in this case.

Thermal Decomposition. An apparatus has been described[93] for studying the kinetics of homogeneous gas reactions at high temperatures and at pressures of several hundred atmospheres. The rate of decomposition of diethyl ether at 426°C. was found to increase rapidly with pressures up to 10,000 cm., and then more slowly. At 14,500 cm. the value attained was approximately 50 times that assumed for infinite pressure. These results seemed to indicate that the number of degrees of freedom varies with the time between molecular collisions. A more accurate investigation[94] of the kinetics of the ether decomposition at pressures up to 260 atmospheres confirmed the previous results[95] and showed that they cannot be brought about by a simple unimolecular change. At the highest pressures used the rate of reaction was still increasing. On the basis of the Rice-Herzfeld free radical mechanism,[96] a qualitative explanation of the data was thought possible, but the reaction was considered too complicated to allow any quantitative comparison with theoretical values.

The formation of olefin and water by the decomposition of diethyl ether vapor on bauxite at 150-300°C. has been investigated by Marx.[97] He used a closed apparatus with continuous circulation of gas. With high ether pressure at the beginning of an experiment and a relatively small volume of catalyst, the activating material adsorbed ether to such an extent that the reaction was retarded by the water formed. This effect was eliminated by circulating the gases over barium oxide. The initial absorption was then followed by a decomposition in two stages: the principal reaction (of the order 0.35)[98] during which ether in the vapor phase was continuously supplied to the bauxite as the action progressed, and a second interval (of the order 3) when the decomposition of the material adsorbed at the active centers took place.

When the experimental conditions were reversed so that a large amount of catalyst was present and the initial vapor pressure quite low, the concentration of the reactant on the activating material was small. Two intermediate steps were then evident: one of zero order[99] corresponding with diffusion from the gas phase and another (of order 1 to 2) during which ether is supplied by the inactive surface.

Both normal and retarded reactions had the same heat of activation, calculated as 31 kg. cal. per mole of diethyl ether. The number of active centers was estimated to be between 2×10^{19} and 10^{20}.

Jaeger[100] reports anhydration of ethanol at 340-380°C. by a sodium-aluminum-borotitanate containing thoria. Other base-exchange materials that have been acid-leached so that the active components are in nonexchangeable form may also be used as catalysts in similar dehydrating reactions.

Deterioration of Anesthetic Ether. In the presence of air, diethyl ether rapidly forms peroxides[100a] and their decomposition products. These substances may be removed from ether, according to Christiansen and Van Winkle,[101] by means of active charcoal (in the absence of oxygen). The addition of a small quantity of a cuprous compound such as cuprous oxide has been recommended for avoiding deterioration during storage.[102] The conversion of diethyl ether into acetaldehyde and a small proportion of acetic acid and its anhydride has been reported by Dreyfus.[103] The reaction took place on heating in the presence of an oxidation or of a dehydrogenation catalyst to 300 or 450°C. By working in the liquid phase, the reaction products could be oxidized to acetic acid.

A study of the deterioration of anesthetic ether has been made by Manikov and Larionov[104] for the purpose of discovering stabilizers and testing their value. They found the commonly used solid potassium hydroxide to be effective against formation of aldehydes and peroxide compounds for 9 months with ether stored in opaque containers but for only 19 days if the liquid was exposed to daylight. In the dark, iron shavings retarded peroxide production and increased slightly the aldehyde content of the samples. In diffused light, ether broke down considerably more rapidly in presence of reduced iron than of the ordinary metal. Preliminary tests indicated storage over solid potassium hydroxide in bottles covered with black paper as the best practical method of preservation. Further work by Goryainova[105] disclosed that any stabilizing effect of iron is possible only when the ether is free from the products of peroxide reduction that are present after the usual purification process. It was found that the anesthetic could be kept without change for 8 to 9 months without use of a stabilizer, if it had been freed from aldehydes and peroxides by partial oxidation with alkaline permanganate followed by treatment with alkaline potassium manganate. Following such purification, iron turnings served to prolong the preservation period considerably.

---

[98] When the decomposition of only one substance is concerned: A reaction of the order n is one in which the rate of decomposition of the original reactant at any time is proportional to the nth power of its concentration at that time.

[99] A reaction of zero order is one in which the rate of reaction is independent of the concentration(s) of the reacting substance(s).

Lott[106] suggests purification of commercial ether by dephlegmation to remove alcohol. He recommends further treatment at 40-50°C. with mercuric oxide by using the latter in aqueous suspension in order to obtain better contact between the ether and the metallic oxide. Cox and Greer[107] advocate that after treatment with sulphuric acid or chlorine and with a bisulphite solution (or oxide of mercury), for aldehyde removal, the ether fraction be subjected to the action of a strong alkali, for example, sodium hydroxide.

In this connection Arup[108] obtained 0.9 per cent residue after active distillation (on a water bath) of a sample of ether which had been kept in dark storage for over 3 years. Another test showed the liquid material to contain available oxygen equivalent to 0.4 per cent hydrogen peroxide. The residue mentioned above exploded violently at 124°C. Similar residues were non-explosive if the ether had been treated with silver hydroxide,[109] dry silver oxide, or if butter fat (0.1 per cent) had been added prior to the evaporation.

Degering[110] notes the tendency to stress the fire-hazard of ether while neglecting the explosive properties of the substance when peroxides are present. He found ethyl, isopropyl and butyl ethers full of peroxides. For testing he uses a slightly acid solution of potassium iodide, shaking equal volumes of it and the ether together (1 cc. of each). If any iodine is liberated, the ether should be purified. He recommends for purification, the addition of 1 volume of 20 per cent sodium hydroxide to 200 volumes of ether, followed by steam distillation of the ether layer.

Williams[111] reports all ethers studied by his organization[112] to have developed peroxides on storage and that, with practically all, explosions have been experienced. He considers the dry distillation of any ether hazardous unless peroxides have been proved absent. Even a small amount becomes concentrated toward the end of a distillation. Any mechanical shock increases the likelihood of explosion. Distillation of "suspected" ethers with steam and maintaining an excess of water with the still residues is recommended for rendering the peroxides harmless.

The use of inhibitors is discussed by Williams, though he does not consider them infallible. He recommends that distillations of any ether should be carried out to dryness only from the safe side of a shatter-proof screen, as the peroxide explosions are usually extremely violent.

The danger attendant on making extractions in the laboratory with peroxide-containing ethers is emphasized by MacCulloch,[113] of the Government Medical Store Depot at Madras, India. It is stated that consignments of several cwt. of ether in 4-oz. bottles would arrive entirely unfit for anesthetic use due to its readiness to develop complex decomposition compounds. Many tests developed the fact that a copper wire (guage #20) placed in an amber storage bottle up to the height of the contents is a preventive for such deterioration. MacCulloch notes that ether protected thus in 1931 had as yet (1936) developed no peroxides.

In 1934, the "Stores" method of anesthetic preservation was altered to the addition of 1 in 5000 of hydroquinone. This renders the ether unsuitable for use in analytical laboratories, however. The presence of copper wire introduces no weighable matter into the substance and avoids the purification necessary before peroxidized ethers can be utilized safely.

In this connection, steel wire, iron filings or precipitated metallic iron have been recommended to inhibit ether decomposition in tin-plated containers used for storage and shipment of the compound.[114]

In the recovery of volatile solvents by adsorbing their vapors in active carbon, it has been noted that traces of peroxides were found only after extended exposure of the saturated adsorbent to atmospheric oxygen.[115] Formation of ethyl peroxides did not occur when alcohol-ether vapor was adsorbed by, or desorbed from, active carbon, regardless of whether iron or oxygen was present.

HIGHER ALCOHOLS AND ESTERS (OR ACIDS) FROM ETHANOL

It has long been known that ethyl alcohol can be readily dehydrogenated catalytically to acetaldehyde in the presence of metals (e.g., copper) at temperatures of 200-300°C. It has been shown that, in addition to acetaldehyde, such substances as *n*-butanol and ethyl acetate may be obtained directly by the decomposition of ethyl alcohol by means of certain specific catalysts. Dolgov and Volnov[116] investigated the decomposition of ethyl alcohol vapor at 450°C. by means of a mixture of the oxides of iron and aluminum precipitated on powdered animal charcoal. A fair yield of *n*-butanol was secured together with various other products, including mixed gases, formaldehyde, acetone, olefins, acetaldehyde, diamyl ether and dibutyl ether. The formation of butanol was interpreted as proceeding according to the equations:

$$C_2H_5OH \longrightarrow C_2H_4 + H_2O$$

and

$$C_2H_5OH + C_2H_4 \longrightarrow C_4H_9OH$$

Secondary reactions, viz.,

$$C_2H_5OH \longrightarrow CO + CH_4 + H_2$$
$$2C_2H_5OH \longrightarrow CO_2 + 3CH_4$$

were considerably checked by activation of the catalyst with lanthanum oxide. With this promoter 22 per cent yields of butanol were possible at 450°C. Lower temperatures decreased the yield of butanol.

DIRECT CONVERSION OF ALCOHOL TO ESTERS

Relatively large conversions of ethyl alcohol into alkyl acetate have been achieved by passage of the former as vapor over copper oxide containing small proportions of difficultly reducible metallic oxides. Thus, Ivannikov and Gavrilova[117] obtained 24 per cent of ethyl acetate when using copper oxide impregnated with 0.1-0.2 per cent of thoria as the contact agent and a temperature of 350°C. The formation of this ester, which reaction could be inhibited by the addition of acetic acid, was regarded as occurring through the condensation of acetaldehyde initially formed. By conducting ethyl alcohol vapor over a copper catalyst, prepared from cupric acetate and containing 0.2 per cent of ceria,[118] Dolgov and his collaborators[119] obtained a 33 per cent yield of ethyl acetate at 275°C. and atmospheric pressure. After returning the gas mixture four times over the catalyst at 250°C., analysis showed the presence of 40 per cent ethyl acetate, 20 per cent acetic acid and 15.5 per cent acetaldehyde. The most active catalyst was one deposited on granular carbon. In further experiments by the same workers,[120] repeated recirculation of the reaction products effected yields of 45 per cent ethyl acetate, 24 per cent acetic acid and 11 per cent acetaldehyde. These results were considered exceptional on comparison with those of 20 per cent ester formation reported by others for similar conversions.

In a detailed study[121] of the factors influencing direct esterification of alcohols the probable mechanism of the reactions involved is discussed by these same investigators.

The catalyst was prepared by slowly introducing cupric acetate solution (containing 0.2 per cent ceric nitrate) into hot concentrated sodium hydroxide solution: the precipitate was washed, dried at 105°C. and reduced with hydrogen at 180-200°C. The material loses one-third of its activity in 18 days and more than half in 28 days. However, it is completely restored by oxidation in dry air at 180-200°C., followed by re-treatment which hydrogen. Substitution of pulverulent for granular carbon as a base for the catalyst decreased ester formation.

Dilution of the ethanol used, beginning with 10 per cent of water, cut down the yields of both ester and acid. Ninety-five per cent ethyl alcohol seemed industrially practical as a raw material.

The effect of each reactant on the catalyst was tested by use of standard reagents treated under esterification conditions. Only the aldehyde had a destructive action.

Distillation of the condensate from treatment of ethanol resulted in the formation of several azeotropic mixtures. At 68-72°C., there was collected a solvent containing 72 per cent acetate and 25 per cent alcohol, but no acid or aldehyde. Ninety-five per cent acetaldehyde had been completely removed by distillation at 20-22°C. A small amount of higher esters (mostly butyl acetate) passed over at 85-90°C. The final fraction, boiling point 110-118°C., consisted of 100 per cent acetic acid; no residue was left in the flask.

Dolgov and his co-workers consider the reaction for ester formation to be that reported by Tishchenko:[122]

$$\begin{aligned}&(1)\quad C_2H_5OH \longrightarrow CH_3CHO + H_2\\&(2)\quad 2CH_3CHO \longrightarrow CH_3CO_2C_2H_5\end{aligned}$$

Attendant small amounts of acetal appearing after single runs could be accounted for by the equation suggested by Geuther:[123]

$$CH_3CHO + 2C_2H_5OH \rightleftharpoons CH_3CH(OC_2H_5)_2 + H_2O$$

Technological problems of large scale procedure according to the method developed by Dolgov and his collaborators are discussed by Beizel, Hel'ms and Lel'chuk.[124]

It was found impractical to recirculate the reaction products on account of poisoning the catalyst by the aldehyde. The latter is to be distilled off at 20-22°C. so that the unchanged alcohol, 40 per cent of the original, can be re-used. On the basis of this recovery, 1 ton (metric) of 95 per cent ethyl alcohol is expected to produce, in a single run, 550 to 600 kg. of solvent ester, 350 kg. acetic acid, 40 to 50 kg. acetal and 25 kg. of gas (97 per cent hydrogen).

Contact decomposition of ethyl alcohol to form hydrogen and acetaldehyde with subsequent condensation of the latter to produce ethyl acetate has been accomplished by Bukreeva-Prozorovskaya and Yanuisheva.[125] At 250°C., the condensate was composed of 60-64 per cent ethyl acetate, 3-6 per cent acetic acid and 3-6 per cent acetaldehyde.

A variation of the above general method of forming organic esters has been found by Guinot[126] to result in reduced yields of acetaldehyde in the final product. Vapors of the primary aliphatic alcohol are passed over a dehydrogenation catalyst maintained at 200-260°C. After a partial condensation of the vapors leaving the reaction chamber, the remaining gases, rich in hydrogen, are continuously recirculated, with additions of fresh alcohol, as needed, through the catalyzing furnace. Reduced copper, carrying titania, thoria or urania as a promoter, functioned as the activator in the production of ethyl acetate from ethanol.

A synthesis of propionic acid from ethanol was attempted by Hardy.[127] Using 200 atmospheres pressure he passed alcohol, carbon monoxide and steam through 87 per cent phosphoric acid containing 2 per cent copper phosphate. Between temperatures of 250 and 370°C., he obtained a product consisting of high-boiling isomers of ethylene, water, ethanol, small amounts of propionic acid and ethyl propionate together with traces of acetaldehyde and volatile hydrocarbons. The polymers of ethylene were formed two or three times as rapidly as the propionic acid. It was thought that pressures of 500 to 1000 atmospheres might give more favorable results.

It may be noted that Ivannikov and Gavrilova[128] find a copper-uranium catalyst suitable for obtaining 50 per cent yields of esters from propanol and butanol. The contact material functions at 220°C. and slowly loses its activity. The reactions are analagous to the above described production of ethyl acetate and hydrogen from ethanol by use of copper catalysts with small additions of ceria or thoria.

The production of butanol from ethanol is effected by Fuchs and Querfurth[129] by passage of ethanol vapor, admixed with hydrogen, over a catalyst containing magnesia and a smaller proportion of copper. Butanol and also higher alcohols are obtained[130] by passage of a similar mixture of ethyl alcohol and hydrogen at 200-350°C. over a catalyst of magnesia containing a smaller amount of another metal or metallic oxide, such as chromic oxide. For example, hexyl, octyl and higher alcohols and ethers were produced by passage of ethanol, butanol and hydrogen in mixture over a catalyst composed of metallic copper, alumina and magnesia. The temperature of the treatment was 350°C. and the pressure maintained was 30 atmospheres. In another case, acetaldehyde and hydrogen, contacted with alumina, calcium oxide and copper at 260°C., gave a mixture of butanol, butyl propionate, butyl acetate and higher alcohols.

Higher alcohols and esters are obtained by passage of certain oxygenated derivatives of paraffins (esters, aldehydes and alcohols other than ethanol or its mixture with methanol) and hydrogen at ordinary or increased pressures over mixed catalysts.[131] The latter consisted of one or more feebly basic oxides. A number of substances were effective for this purpose, viz., alumina, uranium oxide and thoria, in admixture with not more than 10 per cent of copper, silver, nickel or chromium. In some cases the addition of a basic oxide, such as lime, barium oxide, magnesia or lithia, is helpful. Pressures of 1 to 50 atmospheres and temperatures ranging from 150 to 400°C. may be employed. Herrmann[132] describes the conversion of ethyl alcohol into a mixture of acetaldehyde, butanol, acetone, ethyl acetate, ethylene and hydrogen. The ethanol is passed in vapor form at atmospheric pressure over a catalyst consisting of a compound of manganese, magnesium, zinc, iron, barium, strontium, calcium, sodium or copper. The temperature necessary, 420-460°C., is above that best suited to the production of acetaldehyde.

The action of a specially treated dehydrogenating catalyst in combination with a condensing agent has been described by Scott[133] for the conversion in *one stage* of alcohols either to those of higher molecular weight or to esters of the original reactant. One catalyst[134] found effective for making butanol or ethyl acetate from ethanol consisted of a copper compound supported on alumina gel and reduced in hydrogen; at 200 to 240°C., if to be used for ester formation, or at 400 to 550°C. for the production of higher alcohols. In the latter case, the condensing agent, e.g., carbonate of potassium or cesium, is added in a ratio of 1 part to 2 parts catalyst for combination of only 2 molecules of the starting material (alcohol). Higher proportions are necessary for the formation of higher alcohols.

A reaction temperature of 200-230°C. favored longer life of the catalyst and hence its control of the desired end product. The conversions reported were carried out in the liquid phase in a steel bomb, agitated for periods varying from 4 to 22 hours. The pressures used ranged from 150 to 1000 lbs. per sq. in., dependent upon the boiling points of the liquids present and the temperatures employed. Higher alcohol formation was favored by about 100 lbs. per sq. in. added hydrogen. Ester production with hydrogen as a by-product required venting the gas as formed.

Anhydrous alcohols were employed, but supplementary experiments showed that the presence of up to 10 per cent of water did not prevent formation of satisfactory quantities of the end products.

Thus, by heating 450 cc. of dry ethyl alcohol with 35 g. of a reduced catalyst to 220°C. for 22 hours, under pressure, 97 per cent of the alcohol decomposed was transformed into ethyl acetate. A similar treatment at 200°C. was carried out in the presence of the same catalyst after addition of 20 g. of potassium carbonate as condensing agent. Under a hydrogen partial pressure of 100 lbs. per sq. in., 65 per cent of the ethyl alcohol was converted into butanol, 17 per cent into hexanol, 14 per cent into higher alcohols and small amounts of ethyl acetate. Primary or secondary alcohols as well as mixtures were found to respond to this one-stage treatment. It was necessary, however, always to have present two hydrogen atoms on the carbon atom next to the one combined with the hydroxyl group. The following condensations were recorded:

PYROLYSIS OF ESTERS

That the simple ethers are not readily dehydrated to produce olefins is common knowledge A study of the pyrolysis of esters and acetals and certain related substances by Bilger and Hibbert[135] has established some important facts which have a bearing on the chemistry of alcohols and their derivatives:

1. "Ester pyrolysis and reverse reactions are best explained by the 'radical theory' as developed and extended from Nef's dissociation theory."

2. According to experimental evidence "ester pyrolysis does not progress through ether intermediates" and "the olefin derivative comes solely from the alkoxy portion of the ester."

3. "The stability of isomeric esters toward heat is greater for those derived from primary than from secondary alcohols."

4. "Methyl esters, or substituted methyl esters, are much more stable towards heat than either ethyl esters, β-substituted ethyl esters, or the higher alkyl esters."

Results on pyrolysis of ethyl acetate and the isomer ethylene acetal appear in Table 70.

TABLE 70.—*Data on Pyrolysis of Ethyl Acetate and an Isomeric Acetal.*

Material pyrolyzed	Ethyl Acetate	Ethylene Acetal
Temperature	485°C.	485°C.
Total time	65 min.	65 min.

OTHER REACTIONS OF ETHYL ALCOHOL

The conversion of ethyl alcohol into liquid hydrocarbons and other products by the action of heat and pressure has been investigated by Smolenski.[136] Whereas gases were chiefly obtained at 350°C. under pressure, upwards of 80 per cent of liquid products were produced at 400°C. but these consisted mainly of oxygenated compounds. Treatment at 450°C. resulted in a 40 per cent yield of liquids containing a substantial proportion of cyclic hydrocarbons. In the presence of alumina at this temperature, 20-25 per cent of the alcohol was transformed into hydrocarbons, mainly aromatic, though admixed with some naphthenes.

Alkali metal ethylates are obtained by treatment of ethyl alcohol with the alkali metals, hydrogen being evolved. It has been shown by Williams and Bost[137] that, in the absence of water, the reaction between ethyl alcohol and sodium hydroxide was 75-100 per cent complete according to the equation,

$$C_2H_5OH + NaOH \rightleftharpoons C_2H_5ONa + H_2O,$$

after the alcohol-hydroxide mixture had been boiled for 1 hour. Alkali metal alcoholates prepared, for example, by the reaction between dry ethyl alcohol and sodium hydroxide, may be precipitated from the reaction mixture by the use of anhydrous acetone.[138] The mixture is either refluxed or held at room temperature until crystals are formed. The latter may be washed with kerosene and dried in air free from moisture and carbon dioxide.

At high temperatures ethyl alcohol reacts with caustic alkalies with elimination of hydrogen to yield alkali metal acetates. One procedure[139] for making sodium acetate is that of passing ethyl alcohol vapor, at 250-300°C., into a fused equimolecular mixture of alkali hydroxides and acetates. The alkali used is a mixture of sodium and potassium hydroxides in molecular ratios varying from 1:2 to 3:1. After dissolving the reaction mass in water, sodium acetate trihydrate is recovered by crystallization. The mother liquor is evaporated to dryness and the residue fused with more sodium hydroxide for further use.

Aluminum ethylate, and alcoholates generally, are finding important industrial applications, particularly as catalysts in certain organic reactions. A review of the preparation and properties of these interesting compounds has been contributed by Zappi and Restelli,[140] who prepared aluminum alcoholates by the method of Henle.[141] They found that well-cleaned aluminum filings begin to react with anhydrous alcohols at room temperature if mercuric chloride is present. Solubilities in the corresponding alcohols were determined for the alcoholates prepared from the following: methanol, ethanol, propanol (α- and β-), butanol (α- and β-), phenyl methanol and β-propenol. With the exception of the first and last given, the solubilities ranged from 12 to 47 per cent.

Another procedure for the production of aluminum ethoxide, or ethylate, consists in the action of metallic aluminum on ethanol, used slightly in excess.[142] The reaction is carried out at 120°C. in an autoclave. The product may be recovered by vacuum distillation. A yield of 95 per cent is reported as being obtained without the aid of catalysts. According to Seib,[143] the same compound may be made by starting the interaction between metal and alcohol in the presence of a small amount of the alcoholate to be produced. In this instance, the addition should be less than one-fifth of the yield of aluminum ethoxide to be expected from the alcohol treated.

Alcohols and Sulphuric Acid. With sulphuric acid, or pyrosulphuric acid, ethyl alcohol combines to form ethylsulphuric acid, the amount of the latter substance produced being controlled by the equilibrium,

$$C_2H_5OH + H_2SO_4 \rightleftharpoons C_2H_5O \cdot SO_3H + H_2O$$

This reaction was studied by Suter and Oberg[144] who determined the equilibrium constants for ethanol and 96.7 per cent acid at 25 and 35°C.; these values for the lower temperature as well as the extent of esterification for a molar ratio of one are given in Table 71. The value of K (equilibrium constant) for ethyl alcohol and 96.7 per cent sulphuric acid at 35°C. was 1.84.

TABLE 71.—*Reaction of Ethyl Alcohol with Sulphuric Acid at 25°C.*

Acid	Per Cent of $C_2H_5SO_4H$	K
96.7% H_2SO_4	52.6	1.76
H_2SO_4 + 5.2% SO_3	59.8	2.02
H_2SO_4 + 22.6% SO_3	65.1	2.08
H_2SO_4 + 31.98% SO_3	67.7	1.98

The activities of ethylene in concentrated sulphuric acid and of ethanol in dilute sulphuric acid are known from the work of Gallagher and Keyes.[145]

[146] G. N. Lewis and M. Randall. "Thermodynamics," McGraw-Hill Book Company, New York, 1923.

Alcohol and Hydrogen Halides. The preparation of alkyl chlorides by vapor-phase combination of alcohols with hydrogen chloride in the presence of certain catalysts is discussed by Ernst.[147] For example, vaporized ethanol and hydrogen chloride formed ethyl chloride at 240-300°C. when passed over activated carbon which had been impregnated with phosphoric acid.

According to Brooks,[148] ethyl chloride is formed when dry hydrogen chloride reacts with diethyl ether in the presence of anhydrous metallic halide catalysts, such as the chloride of zinc, aluminum or ferric iron. The method of procedure recommended is the passage of the reactants in vapor form over the catalysts. The latter require periodic renewal since they are so chosen as to absorb the water formed in the reaction. Another method for accomplishing the same result is to treat a suspension of the metallic chloride (in ether) with the hydrogen halide gas at a temperature below the boiling point of the ethyl chloride. The temperature used in either case must be below that required to expel water from the catalyst chosen.

An "autothermal" method of reacting ethyl alcohol with a hydrogen halide to produce ethyl chloride has been described by Holt and Daudt.[149] For example, alcohol and hydrogen chloride are passed under definite conditions into a solution of zinc chloride which has its concentration below the equilibrium value at the operating temperature. At 138-140°C. (the equilibrium concentration being 80 per cent) a 70 per cent solution is held constant by allowing the required amount of water vapor to return to the catalytic liquor from the evolved reaction vapors.

By means of a halide of bismuth as catalyst, yields of over 90 per cent ethyl chloride are reported from ethanol and hydrogen chloride.[150] The activator may be used in solution or supported on pumice. Bismuthyl chloride, or the tribromide of bismuth, has been used, e.g., in 70 to 90 per cent aqueous solution. The temperature is held above 110°C., to remove water continuously in vapor form.

In the preparation of ethyl bromide by reaction of ethyl alcohol, sulphuric acid and sodium bromide, the addition of small proportions of metallic copper is said[151] to increase the yield from 57 per cent to 80 per cent. The function of the copper appears to be associated with its reducing action which serves to limit the bromine to its ionic state. No free bromine appeared when the copper was used.

Another process for production of alkyl halides from ethers consists in treating the latter with certain organic halides,[152] viz. those having no hydrogen attached to a carbon next to that combined with the halogen. A small percentage of the corresponding alcohol may be included in the ether. Alumina in granular form or as a gel may serve as the catalyst. Phosphates of cerium, iron, cadmium or aluminum are also mentioned for this purpose. The temperature of reaction is between 270 and 340°C. Chloroform, carbon tetrachloride, di-iodomethane, dichlorophenyl methane or trichloroacetic acid are among the organic halides adapted for furnishing the necessary halogen atoms in the above conversion.

Diethyl thiosulphite, $(C_2H_5)_2S_2O_2$, has been prepared by Meuwsen[153] by the action of sulphur monochloride on sodium ethylate according to the following metathesis:

$$S_2Cl_2 + 2NaOC_2H_5 = (C_2H_5)_2S_2O_2 + 2NaCl$$

The alcoholate used was free from alcohol. The reaction was carried out in a medium of well cooled low-boiling petroleum ether (b.p. 30-40°C.). The ester formed, a greenish-yellow liquid boiling at 62.0-62.7°C. at 16 mm. pressure, was stable to air and moisture. A colorless liquid, considered an isomer and boiling at 67-68°C. at 16 mm. pressure, was obtained by vacuum distillation of the colored product.

Ethyl chlorosulphinate, $SOCl{\cdot}OC_2H_5$, was also prepared. It boiled at 45°C. with 38 mm. pressure and at 171°C. under normal conditions. No isomer was obtained.

Ethyl hypochlorite[154] has been recognized by Suknevich and Chilingaryan[155] as the first product of the action of calcium hypochlorite on ethyl alcohol. The subsequent formation of chloral in this reaction is regarded by these investigators as proceeding according to the following sequence of changes:

$$\begin{gathered} C_2H_5OCl \longrightarrow HCl + CH_3CHO \longrightarrow CH_2{=}CHOH \xrightarrow{C_2H_5OCl} \\ CH_2ClCH(OH)OC_2H_5 \longrightarrow CHCl_2{\cdot}CHO \longrightarrow CCl_3CHO \end{gathered}$$

Deanesly[156] describes the formation of the hypohalites of primary, secondary or tertiary alcohols by introducing a halogen into a mixture of alcohol and aqueous alkali in equivalent proportions, the reaction proceeding as follows:

$$KOH + ROH + Cl_2 \longrightarrow ROCl + KCl + H_2O$$

Ethyl Alcohol and Amines. Ethyl alcohol may be combined with primary and secondary amines under the influence of certain catalysts with the formation of ethylated bases and elimination of water. Catalysts, consisting of alumina, or alumina admixed with other metallic oxides, have been tried for the ethylation of ammonia in the vapor phase.[157] The same results were obtained at 300-400°C. and at atmospheric pressure in the presence of alumina alone or alumina plus 10 per cent ferric oxide. The latter iron catalyst, however, yielded less gaseous by-products. In the direct ethylation of aniline by ethyl alcohol in the vapor phase at 350-400°C. and atmospheric pressure, both mono- and diethylanilines are formed. The results of a series of experiments[158] using a mixture of 1 mole of aniline and 1.45 moles of alcohol are summarized in Table 74.

Adkins and Cramer[159] recommend a catalyst of reduced nickel for the interaction of ethyl alcohol and tertiary heterocyclic amines. For example, ethanol (1 mole) and piperidine (0.5 mole), at a temperature of 200°C. and pressure of 100 atmospheres in the presence of this contact agent, furnished an 80 per cent yield of N-ethyl piperidine. Under similar conditions α-methyl piperidine and the alcohol gave an 84 per cent yield of N-ethyl-α-methyl piperidine.

As catalysts for the direct combination of alcohols with ammonia, or a primary

or secondary amine, phosphoric acid or a phosphate dispersed on a carrier has been suggested.[160] Reaction was effected at 250-500°C. in the vapor phase. The use of oxides, chlorides or sulphates of copper and iron, in the presence of acids or alkaline salts, has also been described for the same purpose.[161]

Other Reactions. Catalytic hydrogenation of toluene by means of ethanol has been accomplished by Shuikin and Feder.[162] When mixed vapors of toluene and ethyl alcohol were led over a nickel-alumina catalyst at 170-210°C., the former substance was hydrogenated and the latter dehydrogenated in accordance with the following reaction:

$$\underset{\text{toluene}}{C_6H_5CH_3} + \underset{\text{ethanol}}{3C_2H_5OH} \rightleftharpoons \underset{\substack{\text{methyl}\\\text{cyclohexane}}}{C_6H_{11}CH_3} + \underset{\text{acetaldehyde}}{3CH_3CHO}$$

The workers considered the most favorable temperature for this metathesis to be 190°C. The best yield was 26 per cent of the theoretical based on an aldehyde-toluene ratio of 9:1. Similar results were possible at 180-190°C. with a catalyst formed by precipitation of platinum on asbestos.

The effect of the electric arc or spark on ethanol vapor has been reported by Petrik.[163] Using zinc electrodes he obtained a mixture of highly calorific gases. The compositions of the yields varied considerably as may be seen from the following figures: hydrogen, 30 to 58 per cent; methane, 6.7 to 29 per cent; carbon monoxide, 22 to 29 per cent; olefins, 9 to 12 per cent.

In the catalytic production of bivinyl (butadiene) directly from ethyl alcohol by the method of Lebedev,[164] *o*-ethylphenol has been identified[165] in the hydrocarbon condensate along with other homologous phenols. Among the by-products of the same conversion further work[166] has disclosed normal primary saturated alcohols of the pentane and hexane series.

THERMAL DECOMPOSITION OF ETHYL ALCOHOL

The catalytic decomposition of ethanol has been studied by Boomer and Morris.[167] Equimolecular proportions of the alcohol and water were passed in vapor form through a vertical autoclave containing the catalyst. The temperatures used were 350, 400, 450 and 500°C. The contact agent was prepared by impregnating silica gel[168] with a concentrated solution of cupric and chromic chlorides (in equimolar proportions) and then drying at 100°C. Afterwards the mass was transferred to a pyrex glass tube and treated with hydrogen for 5 hours at 300°C.

The workers were interested mainly in the appearance of ethane in the gases resulting from the pyrolysis of alcohol. They made no analysis of the small amounts of oily, acidic, aqueous products, which were collected in a water-cooled receiver followed by a condenser maintained at the temperature of a solid-carbon-dioxide-ether mixture. While water vapor exerted a retarding effect on the speed of reaction, it passed through the catalyst unchanged. The gaseous products were analyzed for hydrogen and carbon monoxide (by burning with copper oxide), for methane and ethane (by slow combustion with oxygen) and for carbon dioxide. The results appear in Table 75.

TABLE 75.—*Gaseous Products from Alcohol Pyrolysis Over a Copper-Chromium-Silica Gel Catalyst.*

	Percentage Composition of Gases					
Temp. in °C.	Hydrogen	Carbon Monoxide	Ethylene	Carbon Dioxide	Methane	Ethane
350	6.0	0.7	90.3	0.5	0.7	1.8
400	23.5	0.9	70.0	2.7	0.9	2.1
450	29.4	0.9	53.0	8.6	4.9	3.2
500	40.5	0.9	30.4	10.2	11.2	6.4

Although the catalyst obviously changed from a promoter of dehydration at 350°C. to one possessing dehydrogenation powers at 500°C., the yield of ethane, hydrogen and carbon dioxide increased while that of ethylene decreased. This did not seem to favor a conclusion that the ethane was formed by hydrogenation of ethylene. Carbon was not deposited on the catalyst and the source of the carbon dioxide was not thought to be carbon monoxide. The results appeared to call for further investigation. A series of twenty catalysts, mostly binary, containing nickel and chromium or copper, were prepared and tested for their action on ethyl alcohol solutions in water.[169] The two main types of reaction involved were dehydrogenation and dehydration of the ethanol molecule as indicated in the equations:

$$C_2H_5OH = CH_3CHO + H_2$$
$$C_2H_5OH = C_2H_4 + H_2O$$

Comparison of a large number of runs, carried out as in the previously reported work, indicated that with nickel and chromium mixtures, the combinations behave as two chemical individuals, each having its characteristics dependent upon relative concentrations and mode of preparation. Mixture effects, as such, were confined to secondary reactions and any promoter-effect of one metal on the other in the initial decompositions was either absent entirely or very slight. The apparent order of resistance of the catalysts to deactivation was copper, chromium, nickel. The dehydrating action of the chromium was always apparent. Reactivity and nature of the resultant reactions depended, in general, on the method of preparation of the contact material, chromium requiring severe treatment for activation at all times. The type of reducing agent used had a decisive effect on the secondary reactions in some cases. The most active catalysts for the primary decompositions usually were also effective for the formation of by-products. The action of the nickel always predominated. Subsidiary changes, resulting in the production of carbon, carbon dioxide and complex organic liquids (not analyzed), occurred in practically all cases.

---

[168] For the preparation of the silica gel, see H. N. Holmes and J. A. Anderson, *Ind. Eng. Chem.*, 1925, 17, 280; *J.S.C.I.*, 1925, 44, 399B; *Chem. Abs.*, 1925, 19, 1217.

[169] E. H. Boomer and H. E. Morris, *Can. J. Research*, 1932, 6, 471; *Chem. Abs.*, 1932, 26, 4532; *Brit. Chem. Abs.* A, 1932, 819.

Boomer and Morris[170] have also described experiments in which the temperature was carried up to 500°C. and addition of water or carbon dioxide to the ethanol vapor was practiced to reduce the space velocity of the gaseous alcohol. This was possible since carbon dioxide has been shown to have practically no effect and water vapor a repressing action, if any, upon the primary reactions.

Formation of Methane. A catalyst prepared by the ignition of nickel nitrate on asbestos promoted the aldehydic decomposition reaction. The aldehyde in turn was converted (by thermal decomposition) into methane and carbon monoxide, the latter giving free carbon and carbon dioxide (see Table 76). Similar results were attained with a nickel chromate contact mass.

TABLE 76.—*Thermal Decomposition of Equimolecular Solution of Alcohol and Water with a Nickel Catalyst.*

Temp., °C.	Composition of Gaseous Products Per Cent by Volume						
	CO_2	CO	Total as CO	CH_4	H_2	C_2H_6	C_2H_4

500	20.6	2.0	43.2	45.2	32.2	Nil	Nil

It was believed that the methane came directly from decomposed aldehyde and that hydrogenation of carbon monoxide or dioxide was inappreciable.

However, the hydrogenation reaction was promoted by other catalysts prepared as follows:

A. Four moles chromic oxide, 1 mole zinc oxide, 0.5 mole alumina with traces of copper powder and sodium carbonate. After mixing, grinding to a paste and drying, the very hard material was treated with hydrogen at 300-350°C.

B. One mole zinc oxide, 1 mole chromic oxide, 0.5 mole cupric oxide with a trace of copper powder, treated as above.

C. An equimolar mixture of potassium chromate, nickel nitrate and ferric nitrate were co-precipitated in slightly alkaline solution, the liquor decanted, the precipitate washed, dried at 110°C., and reduced at 300-350°C.

The results secured with these activators appear in Table 77. The liquid prod-

[170] E. H. Boomer and H. E. Morris, *Can. J. Research*, 1934, **10**, 743; *Chem. Abs.*, 1934, **28**, 4972; *Brit. Chem. Abs.* **A**, 1934, 1199.

ucts contained a high-boiling oily fraction. The absence of free carbon formation was considered to render the ethylene an unlikely source of methane and the most reasonable mechanism for its presence was held to involve hydrogenation of carbon dioxide. Both these gases (hydrogen and carbon dioxide) were present in large proportions and their interaction is not inhibited by water. Results with catalyst C (when any aldehyde formed was obviously not decomposed and the ethylene not polymerized) seemed to verify the above conclusions especially as this catalyst did not even hydrogenate the carbon dioxide to produce methane.

Formation of Ethane. The two reactions considered as possible explanations for the presence of ethane (during pyrolysis of alcohol) were both found by Boomer and Morris to occur in proportions controlled by experimental conditions:

1. Hydrogenation of the primary product, ethylene, by nascent hydrogen.[171]
2. Autoxidation and reduction of the alcohol, giving ethane directly.[172]

$$2C_2H_5OH = CH_3CHO + H_2O + C_2H_6$$

A comparison of results obtained in treatment of absolute alcohol with those secured when water vapor or carbon dioxide gas were present is given in Table 78. The same catalyst was used in each case, viz., 75 per cent nickel and 25 per cent zinc, precipitated by sodium hydroxide from a solution of the corresponding nitrates. The effect of oxidation and reduction of the activator between experiments is likewise shown.

TABLE 78.—*Thermal Decomposition of Alcohol Vapor Using a Nickel-Zinc Catalyst.*

	Catalyst Oxidized and Reduced				
	275	0.2	56.5	1.9	0.37

The primary formation of ethane with the nickel-zinc catalyst is indicated by the data in Table 79. The diluents were used to reduce the space velocity of the gases and at the same time decrease the volume of alcohol decomposed. With carbon dioxide present the actual relative yield of ethane was much above that shown by the analyses owing to inclusion of the neutral gas. Any water vapor tends to cut down the quantity of alcohol contacting the catalyst so that the degree of reactivity is lessened. Both of these effects were absent in the case of absolute alcohol.

TABLE 79.—*Thermal Decomposition of Alcohol Vapors Diluted with Carbon Dioxide.*

Catalyst Used	Temp., °C.	Composition of Gaseous Products Per Cent by Volume C_2H_4	H_2	C_2H_6	Space Velocity
D	450	2.5	35.6	4.3	50
	450	2.9	35.3	2.7	25
E	350	0.6	14.6	5.5	50
	450	1.8	36.5	9.1	30
	450	2.6	33.3	2.3	50
F	350	0.2	2.3	3.0	25
	450	1.6	27.4	8.7	25
G	450	1.0	36.1	8.6	25
	450	0.4	11.0	2.4	100
H	450	0.6	25.6	7.7	25

Catalysts:

(D), an equimolecular mixture of zinc oxide and chromic oxide triturated in water and dried at 110°C.

(E), copper and chromium with the addition of nickel were precipitated on silica gel.

(F), 10 moles of magnesium to 1 of chromium were precipitated from a solution of their nitrates by the use of ammonium hydroxide.

(G), 1 mole of cupric hydroxide was precipitated from cupric chloride solution by sodium hydroxide. One-tenth mole of manganese dioxide was added as a promoter.

(H), cupric hydroxide, made as above, with incorporation of one-twentieth mole each of titanic acid and molybdic acid as promoters.

The investigators consider the above results as definitely pointing to ethane formation by hydrogenation of ethylene. The temperature effect is noticeable on comparison of data for catalysts (E) and (F). Influence of space velocity may be seen by comparing the data obtained with catalysts (E) and (G), viz., the higher the velocity, the lower the ethane content because of the shorter time the gases are in contact with the catalyst.

Formation of Carbon Dioxide. This took place several times under conditions considered to preclude the decomposition of carbon monoxide as a secondary reaction product. Sometimes gases made up largely of hydrogen and carbon dioxide were obtained accompanied by an oily condensate; at other times the same gaseous mixture occurred without oily condensates.

Lazier and Adkins[173] have suggested formation of ketene, as a secondary reaction, from the aldehyde primary decomposition of ethanol when a dehydrogenating catalyst is employed. Combination of ketene with aldehyde would give carbon dioxide, leaving an unsaturated hydrocarbon. The latter, on polymerizing, could furnish the resin obtained in certain pyrolyses of ethyl alcohol. These possibilities are evident from the reactions,

$$CH_3CHO \longrightarrow H_2 + CH_2{=}CO$$
$$CH_2CO + CH_3CHO \longrightarrow CO_2 + CH_2{=}CHCH_3$$

Boomer and Morris have identified two types of oils from their condensates. One, a pure hydrocarbon of high molecular weight and empirical formula, C_2H_4, was considered as a possible result by way of ketene formation or by ethylene polymerization. Catalyst (F) produced this type of polymer (see Table 80).

The other oil identified in these pyrolysis experiments had an empirical formula, C_5H_8O, and appeared to be a polymer. This oil, when tested for its molecular weight by the cryoscopic method with benzene as solvent, yielded a value of 240, corresponding to a trimer, i.e., $(C_5H_8O)_3$. It was secured after pyrolyzing alcohol and water mixtures, whereas the hydrocarbon oil resulted from treatment of absolute alcohol.

Catalysts:
(A) and (C) were those employed in experiments given in Table 77.
(E) and (F) were described in Table 79.

In the analyses of the gaseous products in these cases (see Table 81), the relatively low yields of carbon monoxide and methane were considered the result of slight secondary decomposition by the primary acetaldehyde product. The high percentages of hydrogen, indicating excessive dehydrogenation, have led Boomer and Morris to explain formation of these oils as resulting from decomposition of ketene into carbon dioxide and allene, i.e.,

$$2H_2C{=}CO \longrightarrow CO_2 + H_2C{=}C{=}CH_2$$

The latter is known to be very reactive chemically, so that condensations might be expected: for example,

$$H_2C{=}C{=}CH_2 + H_2O = (CH_3)_2CO$$

The resultant compound, acetone, is known to condense when certain catalysts are used. Similarly, the investigators point out that an addition reaction between allene and acetaldehyde could lead to a product of formula $(C_5H_8O)_x$.

Catalysts:
(J), normal zinc chromate, precipitated from zinc nitrate solution by potassium dichromate.
(K), 5 moles of zinc hydroxide and 1 mole of chromic hydroxide precipitated from the nitrates by potassium hydroxide.
(L), contained iron, copper, manganese, phosphorus and potassium.
(M), was composed of iron, copper, manganese, boron and potassium. Both L and M were prepared by the method of Audibert and Raineau.[174]

---

[174] E. Audibert and A. Raineau, *Rev. ind. min.*, **1928**, No. 182, 286; *Ind. Eng. Chem.*, **1929**, **21**, 880; *Brit. Chem. Abs.* **B**, 1929, 840; *Chem. Abs.*, 1929, **23**, 2094, 5091.

A third type of reaction took place on use of catalysts (J), (K), (L) and (M) with absolute alcohol vapor. Here the liquid products contained no high-boiling fractions and carbon was not deposited in appreciable amounts on the catalysts. This absence of carbon and the small yields of methane and carbon monoxide compared with the production of carbon dioxide led the workers to suggest the following successive hydration reactions to account for carbon dioxide and hydrogen formation:

$$C_2H_5OH + H_2O = 2CH_3OH$$
$$CH_3OH + H_2O = CO_2 + 3H_2$$

It was noted, however, that (1) no methyl alcohol was found among the reaction products; (2) the first reaction has not been shown to occur, although methyl ether (isomeric with ethanol) has been thus hydrated; (3) the second reaction may take place in two stages, with intermediate formation of carbon monoxide, although this oxide was found in such small amounts as to render the occurrence of any such action somewhat improbable.

ALCOHOL AS SOLVENT

New uses for ethyl alcohol as a solvent are being found constantly. Hubert and Lambert[175] add ethyl alcohol or gasoline-alcohol mixtures to bituminous coatings, such as asphalt, bitumen, petroleum or coal distillates. It is reported that the covering materials are thus rendered more adherent to dry or wet surfaces.

Klein[176] extracts oil and coloring substances from wax by a composite solvent made by mixing a formate of a lower aliphatic alcohol and another organic material in which asphaltic substances are more soluble than in the formate.

In a method for refining montan wax,[177] after the crude material has been saponified, alcohol, or an alcohol-acetone mixture, is used to dissolve higher alcohols and soaps from the saponified product. The asphaltic constituents are unaffected by the ethanol solvent.

Ethyl esters having a boiling point between 85 and 158°C., such as ethyl isovalerate, propionate and butyrate, serve as diluents[178] when lubricating oils are dewaxed by chilling processes.

ANALYTICAL REACTIONS FOR ETHYL ALCOHOL

Binary mixtures of ethyl alcohol and water are readily estimated by density determinations, or, in very dilute aqueous solution, by chromic acid oxidation.

Estimation of ethanol in dilute aqueous solution is carried out by Vansheidt and Eremeeva[179] in the following manner. The alcohol is converted into ethyl nitrite by treatment with sodium nitrite solution and phosphoric acid. A stream of carbon dioxide-free air, passed through the solution at 35°C., serves to propel the alkyl nitrite fumes through a heated copper spiral in a combustion tube where they are partly burned. Any unburned fumes are oxidized at 135-140°C. in successive concentrated sulphuric acid solutions of silver dichromate and potassium dichromate, so that the original nitrite is entirely converted into carbon dioxide. The latter is absorbed in 50 per cent caustic potash solution, the gain in weight representing the carbon dioxide equivalent of the alcohol in the sample. Although small amounts of acetaldehyde are reported unobjectionable, it is stated that any ether present in the sample should be removed by aeration before the analysis is attempted.

Most of the analytical reagents employed in the examination of technical ethyl alcohol are specifically designed for the detection, or estimation, of small amounts of various impurities, including benzene, methyl alcohol and acetaldehyde.

For detecting traces of benzene (1 vol. in 10,000) in alcohol, Lansing[180] recommends dilution with aqueous sodium sulphate and extraction with carbon tetrachloride. The extract is treated with nitrating acid, the carbon tetrachloride is subsequently evaporated, and caustic soda solution and acetone are added to the residue. A red color (with purple tinge) in the top layer indicates benzene. Similarly, toluene gives a slightly brownish yellow and xylene a definite, but not intense, green.

Differences in density and oxidation behavior serve as the basis of a method, reported by Maricq,[181] for estimating mixtures of ethyl and methyl alcohols.

Brown[182] has described a color reaction with vanillin for the detection and approximate estimation of methyl, isopropyl and amyl alcohols in ethyl alcohol.

A method for the identification and estimation of ethyl alcohol in a mixture of organic materials containing higher alcohols has been elaborated by Nicloux.[183]

For the estimation of alcohol in small quantities of biological fluids, Webb[184] reports a modification of Agulhon's[185] reaction. The accuracy of the determination is said to be within 2 per cent of the actual amount present.

A method applicable to the determination of the alcohol content of physiological fluids and tissues as well as biological culture media has been developed by Friedmann and Klaas.[186]

A procedure for analyzing hydrocarbon-containing alcohols, as employed by the Customs Laboratory of Ottawa, is described by Hoff.[187] For the same purpose Bonnier and Juge-Boirard[188] employ a physical method of analysis based on water-tolerance determinations at different temperatures.

Recovery of alcohol used in the estimation of acidity in dark and bright petroleum distillates has been carried out by Ter-Akopova.[189] A system of rectification rendered the alcohol fraction boiling at 78.3°C. and the alcohol-benzene fraction collected at 68-78°C. available as solvents in making further tests; the former for acidity in dark petroleum, the latter for the same determination in bright petroleum products.

Tests of Absolute Alcohol. Absolute alcohol produced by azeotropic methods frequently contains traces of benzene as well as water. For the estimation of these small amounts of impurities, Swietoslawski and Szmigielska[190] have developed a method based on the following facts: (1) the boiling point of the binary alcohol-benzene azeotrope is appreciably lowered by small amounts of water; (2) benzene in small amounts also changes the boiling point of the alcohol-water azeotrope.

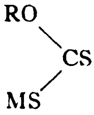
When treated with pulverized potassium hydroxide and carbon disulphide, ethyl alcohol yields potassium ethyl xanthate, mp. 215.3°C., which can be quantitatively titrated with iodine. Other alcohols give analogous xanthates.[191]

The direct titration of xanthate solutions with iodine is based upon the reaction,

$$I_2 + 2C_2H_5O\cdot CS\cdot S^- = 2I^- + (C_2H_5O\cdot CS\cdot S)_2$$

i.e., 2 moles of xanthate are equivalent to 1 mole of iodine. The general formula for a xanthate is



where *R* represents an alkyl radical and *M* an alkali metal. It is obvious that in the quantitative estimation of a xanthate, the amount of standardized reagent used per gram of xanthate depends upon the molecular weight of *R*. Hence, the investigators were able to assign to each alcohol an "alkali reagent number," which sharply characterizes the alcohol. This number for ethyl alcohol is 793 (calculated).

Isomeric alcohols have the same xanthate iodine equivalent, in which case a comparison of the melting points becomes necessary.

The alkali xanthates form in the presence of water so that the alcohol to be tested need not be anhydrous. The method may also be applied directly to a solvent mixture, provided only one alcohol is present.

Chapter 14

Reaction between Sulphuric Acid and Propene. Production of Isopropyl Alcohol

The commercial manufacture of isopropyl alcohol from propene in cracking gas was initiated in 1919-1920[1] employing the process of Ellis and his associates.[2] Later, this alcohol was produced on a small scale[3] at Okmulgee, Oklahoma. In 1925-1926 isopropyl and other secondary alcohols were made for a short time[4] at Tiverton, Rhode Island, and afterwards at Barnsdall, Oklahoma. These plants continued in operation until 1932, when the manufacturing interests were merged. Isopropyl alcohol (as well as other secondary and tertiary alcohols) is being prepared in large quantities at Bayway, New Jersey.[5] Propene employed for this purpose should be free from higher olefins and also sulphur compounds, although paraffin hydrocarbons do not interfere except as diluents. Originally, gases containing both ethylene and propene were employed, the latter being selectively absorbed in diluted sulphuric acid of controlled concentration. At the present time, however, a propene-propane fraction (substantially free from butenes) is employed. This mixture is obtained as an overhead gas in stabilizer operation.

REACTION BETWEEN SULPHURIC ACID AND PROPENE

When propene is contacted with 90 per cent sulphuric acid at room temperature, or with more concentrated acid at lower temperatures, the main reaction products are the mono- and di-isopropyl esters of the acid: viz. $(CH_3)_2CHSO_4H$ and $[(CH_3)_2CH]_2SO_4$, respectively.[6] It has been shown[7] that the corresponding *n*-propyl derivatives are not formed even in the presence of peroxides. Since the latter had been reported to have a directive effect on the addition of hydrobromic acid to certain unsaturated hydrocarbons[8] it was considered probable that at least partial conversion to *n*-propyl sulphates might take place when peroxides were included in sulphuric acid treatment of the olefin.

The alcohol prepared from the above isopropyl esters, by hydrolysis and subsequent distillation, is accompanied by a small proportion (less than 0.2 per cent) of 4-methylpentanol-2, $(CH_3)_2CHCH_2CHOHCH_3$. The latter compound evidently results from the hydration of 4-methylpentene-2, $(CH_3)_2CHCH_2CH{=}CH_2$, produced by dimerization of propene. Such polymerization should be avoided, as it not only leads to loss of raw material, but often necessitates separation and disposal of undesirable oily substances.

[6] Earlier work on this reaction and its industrial applications are discussed by Carleton Ellis, "The Chemistry of Petroleum Derivatives." The Chemical Catalog Co., Inc., 1934.

[7] B. T. Brooks, *J.A.C.S.*, 1934, 56, 1998; *Brit. Chem. Abs.* A, 1934, 1198; *Chem. Abs.*, 1934, 28, 6697.

[8] For the effect of peroxides on the addition of halogen acids to olefins, see Chapter 12.

Since the rate of propene absorption in dilute sulphuric acid does not fall off rapidly with increasing reaction,[9] Brooks[10] suggests the following interactions as taking place in the acid liquor:

(a) monoalkyl esters are first formed as monohydrates of sulphuric acid;

(b) dialkyl esters result from the elimination of water when one mole of hydrate further combines with one mole of olefin.

Production of isopropyl esters, according to this view, is indicated by the equations:

$$C_3H_6 + H_2SO_4 \cdot H_2O \longrightarrow C_3H_7SO_4H \cdot H_2O$$
$$C_3H_7SO_4H \cdot H_2O + C_3H_6 \longrightarrow (C_3H_7)_2SO_4 + H_2O$$

The preparation of isopropyl alcohol from propene involves two separate operations: (1) absorption of the olefin in diluted acid to yield an acid liquor containing isopropyl sulphates, and (2) dilution of the latter with water to effect hydrolysis of the esters, followed by distillation to recover the alcohol.

Absorption of Propene in Sulphuric Acid. The velocity of gaseous propene absorption at 15°C. in sulphuric acid of concentrations varying from 75 to 88 per cent has been studied by Pigulevskii and Rudakova.[11] They found combination to proceed in accordance with the law of unimolecular reactions. The quantity of olefin taken up by unit surface in unit time was proportional to its partial pressure and independent of its concentration, as was also true with ethylene.[12] Furthermore, absorption of propene was found to be autocatalytic. It was also noted that the rate of solution was increased by the presence of silver salts, but much less so by those of vanadium, uranium and tungsten. All of these inorganic compounds exerted less catalytic effect with propene than with ethylene or the butenes. Remiz[13] also reports that a small proportion (3 per cent) of argentic compounds are helpful. However, he employs higher temperatures (110°C.) and more dilute acid (54 per cent). The yield of alcohol is said to be 21 per cent.

The influence of a number of inorganic substances, as well as organic diluents, on the velocity at which unsaturated hydrocarbons are dissolved in sulphuric acid has been investigated by Markovich, Moor and Dement'eva.[14] They likewise observed that salts of silver were the most effective catalysts, and in some instances other compounds exerted an inhibitory action. The organic liquids which were soluble in the acid were practically ineffective except acetone and propionic acid. The presence of acid-insoluble liquids greatly accelerated solution of the gaseous olefins, but chemical interaction took place only when emulsions were formed.

In the commercial production of isopropyl alcohol, sulphation may be accomplished by contacting the olefinic gases with relatively concentrated acid or by treating propene (or propene fractions) under sufficient pressure to maintain liquid-phase conditions. In carrying out gas-phase reaction at low working pressures, the use of an absorbent mineral oil, as proposed by Lebo,[15] greatly increases the capacity of the operating system. In a typical process of this kind, a gas containing 16 to 18 per cent of propene is treated with sulphuric acid and an absorbent oil in a steel tower provided with cooling coils. Interaction is normally prolonged until the liquor contains a substantial proportion of diisopropyl sulphate.[16]

---

[9] Considered an indication that there is no increase in the proportion of water to uncombined acid.

Effect of Catalysts. It is stated by van Peski[17] that combination of propene with acid, e.g., 90 per cent sulphuric, may be effected without polymer formation. This he seeks to accomplish by having present in the liquid medium cuprous cyanide or complex copper salts, for example those formed by reaction of cuprous oxide and carbon monoxide or nitric oxide. Catalysts, such as platinum deposited on carbon black or sulphuric acid-soluble salts of iron, nickel, cobalt or silver, are also mentioned for the same purpose and as stabilizers of acid liquors containing isopropyl sulphates.[18] They are reported, too, of assistance in the absorption of propene.[19] Cyanides of iron, nickel or cobalt are likewise suggested for catalyzing the production of olefin sulphates.[20]

According to Dreyfus,[21] propene is absorbed by 90 per cent sulphuric acid which contains 5 per cent of a sulphonic acid or an organic ester of an inorganic acid.[22] Addition of contact agents such as metallic silver or copper was found beneficial; sulphates of calcium, lead, silver, iron or mercury were also used. Among the organic esters recommended were the monosulphuric acid ester of glycol, sulphuric esters of glycerol, hydroxystearo-sulphuric acid, sulphoricinoleic acid, sulphoaromatic stearic acids, and phosphoric esters of glycol or glycerol. Sulphuric acid, he reports, may be substituted by phosphoric acid.

Effect of Rapid Agitation. A special mixer equipped with paddles and rotated at 600 to 1000 r.p.m. was constructed by Dakin and Gutuirya[23] for atomizing acid employed in the extraction of olefins from cracking gases. Working at atmospheric pressure with 90 per cent acid (which selectively removed only propene) 4 to 4.2 kilograms were used for each kilogram of isopropyl alcohol produced. In tests with ethylene, the application of pressures up to 15 atmospheres was found to lower acid consumption by one-third per unit of alcohol obtained.

Effect of Pressure. By utilizing acids weaker than sulphuric, e.g., phosphoric or organic sulphonic acids, Dreyfus[24] prepared isopropyl alcohol (and ether) from propene at high temperatures and pressures. Contact substances, such as metallic silver, silver sulphate, cuprous oxide, and the sulphates of calcium, iron, lead or mercury were found active. Pressures of 30 to 200 atmospheres and temperatures of 150° to 300°C. were required when the concentration of the absorbing liquid was 40 to 75 per cent. Moisture for hydrolyzing the resultant esters was introduced in vapor form.

ACID ABSORPTION OF MIXED OLEFINS

In treating a mixture of unsaturated hydrocarbons for the production of both ethyl and isopropyl alcohols, Dreyfus and Groombridge[25] propose combination of propene selectively with about 87 per cent sulphuric acid at 20° to 23°C. They then esterify the residual olefin (ethylene) with acid of 75 to 85 per cent concentration at 90° to 130°C. According to Groombridge,[26] only the higher olefin is extracted by employing 70 to 90 per cent acid at 15° to 25°C. and a gas pressure of 10 to 30 atmospheres. Addition of water to the acid liquor as esterification proceeds may be utilized to maintain a constant concentration of the acid phase.[27]

In a process disclosed by Merley,[28] cracking gases are passed into concentrated sulphuric acid (*d* 1.84) at −15°C. until the density falls to less than 1.263. The solution thus obtained is further treated, at the same low temperature, with the liquid hydrocarbons produced by cracking. The resultant liquor contains chiefly isopropyl acid sulphate and is free of organic sulphonic acids. After hydrolysis, the recovered acid may be concentrated and reused. A mixture of equal volumes of glacial acetic acid and hydrogen sulphate containing a few per cent of water has been proposed by Woolcock[29] for selective reaction with propene at 40°C. The liquid medium is afterwards heated to secure isopropanol. Some isopropyl acetate is formed simultaneously.

Lacy[30] treats olefinic gases by countercurrent washing with 60 to 87 per cent sulphuric acid at 35° to 65°C. The liquid at the base of the scrubbing tower may be separated from polymers (if present) and recirculated until its effective alcohol concentration is about 40 per cent.

Another procedure,[31] especially applicable for the treatment of cracking gases containing butenes and lower olefins, is as follows: the gases are first subjected to the action of cuprous chloride, dissolved in aqueous ammonium chloride, to eliminate any diolefin (butadiene) without polymerizing it.[32] Tertiary olefins are next removed by 60 to 65 per cent sulphuric acid at 25°C. or lower. Following this, the *n*-butenes are reacted with slightly more concentrated acid (65 to 70 per cent) at somewhat higher temperatures (35° to 60°C.). Residual propene is thereafter absorbed in acid of 80 to 85 per cent strength, but at 20° to 40°C.

CONTINUOUS METHODS FOR HYDRATING PROPENE

An interesting procedure for the preparation of isopropyl alcohol comprises contacting the corresponding olefin, under slight pressure, with relatively dilute sulphuric acid.[33] From time to time, the condition of the reacting liquor was measured (after cooling with ice water) by direct titration, using bromthymol blue as an indicator. At first the acidity diminished, but later (on continued treatment with the olefin) increased, until finally, practically all the acid originally present reappeared in the free state. This phenomenon seemed to indicate direct hydration of the olefin to alcohol as an overall effect. In a process utilizing such conditions, the free alcohol may be extracted with an acid-resistant solvent such as phenol, cresol, anisole or phenetole. The acid solution is then available for reuse after addition of sufficient water to adjust its concentration. The necessity for reconcentrating the absorbing medium is thus eliminated.

[32] The removal of diolefins from gaseous mixtures is discussed in Chapter 4.

[33] French P. 799,704, 1936, to Usines de Melle (Soc. anon.); *Chem. Abs.*, 1936, **30**, 8240.

Production of isopropyl alcohol by the above method may be carried out under 3 atmospheres pressure. Sulphuric acid, of 75 per cent concentration, containing 0.5 per cent of cuprous oxide, or of lead, bismuth, silver or gold as catalyst, is employed. After absorption is complete, the liquid product is transferred to another vessel for extraction with 3 times its volume of butylcresol. When the latter operation is complete and stratification has occurred, the aqueous layer is withdrawn and returned to the absorption unit of the system. The cresol layer, containing about 50 grams of isopropyl alcohol per liter of solution and a small proportion of acid, is subjected to washing with a small quantity of water. It is then fractionated to furnish a distillate consisting of the binary isopropanol-water azeotrope and a residue of butylcresol. The latter, after cooling and removing any water which separates, is reverted to the extraction unit. This process is illustrated diagrammatically in Fig. 103.

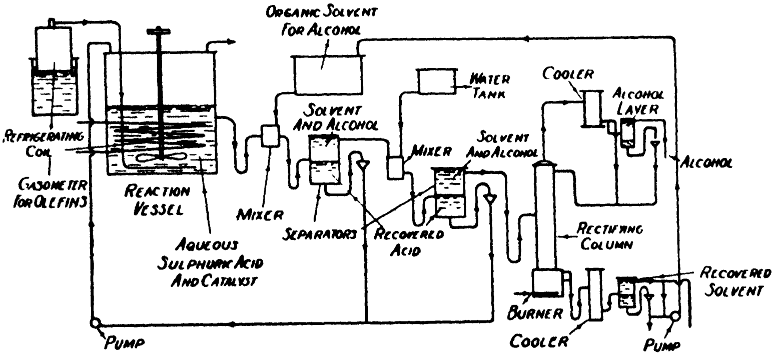

FIG. 103.—Continuous Method for Hydration of Propene to Isopropyl Alcohol. (Usines de Melle, Soc. anon.)

ISOPROPYL ETHER

As previously mentioned, isopropyl ether is sometimes obtained as a by-product in the preparation of isopropyl alcohol. Under appropriate conditions, however, this ether may be the principal substance resulting from the interaction of sulphuric acid and propene. For example, the olefin (under 3 to 7 atmospheres pressure) may be treated in a countercurrent manner in a packed tower with 75 per cent sulphuric acid at 75° to 125°C.[34] Unreacted gaseous paraffins (if present) escape at the top of the tower while at the base is withdrawn the acid solution containing absorbed propene. The liquid medium, after passing through heat exchangers (for preheating fresh acid), is subjected to distillation.

[34] French P. 793,482, 1936, to Standard Alcohol Co.; *Chem. Abs.*, 1936, 30, 4516.

The latter operation yields vapors of isopropyl ether admixed with some propene and isopropanol. These are conducted through a scrubbing tower containing alkali (e.g., sodium carbonate) and thence to a rectifying column, which effects separation into olefin, ether and alcohol. The olefin is returned to the absorption unit, while the alcohol is either withdrawn from the system or is mixed with acid liquor and redistilled. Recovered acid from the last-named step is employed again in the treatment of olefinic gases. A diagrammatic sketch of this process is shown in Fig. 104.

DIISOPROPYL SULPHATE

When propene, under a pressure of several atmospheres, is contacted with sulphuric acid of about 85 per cent strength at 15° to 20°C., the main reaction product is diisopropyl sulphate.[35] Thus, Brooks and Cardarelli[36] accomplish practically complete sulphation of the olefin by treating it under a pressure of 100 lb. per sq. in. with 80 per cent acid at 25°C. The advantage of carrying the reaction to the di-ester stage is that acid consumption per unit of isopropanol produced is thereby reduced and reconcentration costs correspondingly diminish. Moreover, by operating under sufficient pressure, liquid propene (or propene-propane mixtures) may be utilized and interaction prolonged for a considerable period of time in relatively simple equipment.

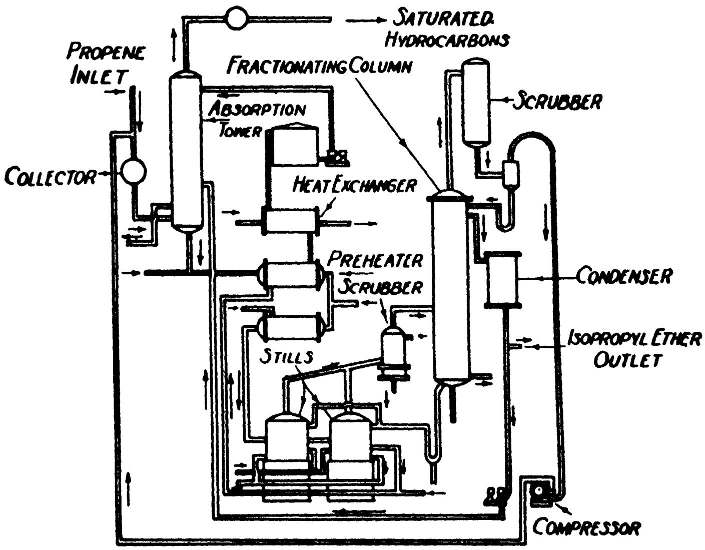

FIG. 104.—Diagrammatic Sketch of Process for Production of Isopropyl Ether. (Standard Alcohol Co.)

Another process comprises combination of the unsaturated hydrocarbon, under

20 atmospheres pressure, with 90 to 100 per cent acid at 70° to 80°C.[37] The resulting ester may then be separated by distillation under reduced pressures, e.g., not over 20 mm. of mercury. This material is afterwards hydrolyzed and isopropyl alcohol recovered by fractionation. The dilute acid obtained by these steps is described as free from carbonaceous bodies and ready for reconcentration. It is reported that the above procedure avoids ether formation during hydrolysis.

Liquid-Phase Absorption

An apparatus for effecting liquid-phase reaction has been described by Young.[38] He suggests forcing a mixture of liquid propene and 80 to 100 per cent acid through an extended flow-path of constricted cross-section. The operating temperature is kept below 40°C. For example, 93 per cent sulphuric acid and liquid hydrocarbons (containing 95 per cent propene) are conducted through a 35-foot coil of steel tubing (1/8 inch bore and 1/4 inch external diameter) under a pressure of 200-400 lb. per sq. in. The temperature in this instance was maintained between 0° and 5°C. The hourly rates of flow of acid and hydrocarbons were 671 grams and 312 grams, respectively. The products consisted of a gas containing 50 per cent propene and a clear acid liquor containing 28.6 per cent of isopropyl sulphates. Hydrolysis of the latter was accomplished by addition of ice. Distillation yielded over 90 per cent of the reacted olefin in the form of isopropanol.

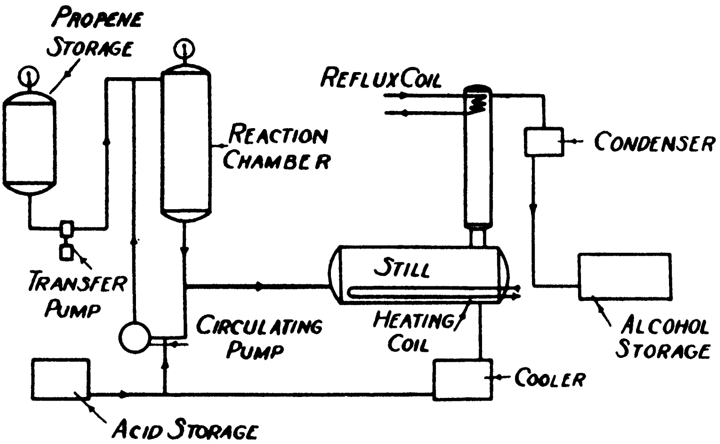

Fig. 105.—Flow Diagram for Liquid-phase Reaction of Propene with Sulphuric Acid. (W. H. Shiffler, M. M. Holm and W. P. Anderson)

Shiffler, Holm and Anderson[39] recommend the use of 50-85 per cent sulphuric acid and temperatures of less than 50°C. The most favorable concentration is 70 per cent by weight. Conversion of the olefin to alcohol may be effected by circulating the liquid reactants under pressure through a lead-lined vessel. For propene-propane mixtures a gage pressure of 125 lb. is sufficient. One type of apparatus which may be employed is illustrated in Fig. 105. The effect of various concentrations of acid on the absorption of the unsaturated hydrocarbon is shown in Table 82.

TABLE 82.—*Effect of Acid Concentration on Propene Absorption from Liquefied Propene-Propane Mixtures. Gage Pressure, 125 lb.*

Sulphuric Acid Used		Liquid Hydrocarbon Mixture			
Gals.	Conc.	Gals.	Propene Content	Period of Reaction	Propene Absorbed
61	73%	77	52.8%	2 hrs.	91%
80	67.8%	100.5	55%	4.5 hrs.	84%
80	65.5%	100.5	55%	5 hrs.	52%

Since the temperature rises somewhat during interaction, provision is made to hold the contact vessel below 50°C. Under these conditions no oily polymers are formed.

After absorption is completed, the acid liquor is withdrawn, diluted with water to about 50 per cent acidity and subjected to steam distillation to recover the alcohol. Reconcentration of the acid to the requisite 70 per cent was effected in the still after removal of isopropanol. In addition to the latter product, some propene (resulting from dehydration of alcohol) and isopropyl ether were obtained. The relative proportions of alcohol and ether depend upon the acid concentration in the distillation unit, stronger acid being conducive to ether formation.

HYDROLYSIS OF ISOPROPYL SULPHATES

As in the case of ethyl esters of sulphuric acid, isopropyl sulphates, although fairly stable in water at ordinary temperatures, are readily hydrolyzed on heating. The rate of hydrolysis is greatly accelerated by the presence of sulphuric, or other, acid. With moderate concentrations the following equilibria are probably set up:

$$C_3H_7SO_4H + H_2O \rightleftharpoons C_3H_7OH + H_2SO_4$$
$$(C_3H_7)_2SO_4 + H_2O \rightleftharpoons C_3H_7SO_4H + C_3H_7OH$$

However, on dilution with the quantity of water usually employed in industrial practice, approximately complete conversion of the esters to the corresponding alcohol is attained. From diisopropyl sulphate, which is generally present in substantial amounts in the liquor from absorption operations, a certain proportion of diisopropyl ether may be produced, according to the equation:

$$(C_3H_7)_2SO_4 + C_3H_7OH \longrightarrow (C_3H_7)_2O + C_3H_7SO_4H$$

Formation of ether may be minimized by removing the dialkyl sulphate and hydrolyzing it separately. In such instances, the concentration of the resultant alcohol should be maintained as low as possible, e.g., by distilling it off as fast as it is formed.[40]

Another by-product of the hydrolysis of isopropyl sulphates in acid solution is propene, probably from dehydration of isopropanol. This side-reaction is almost eliminated by the use of 35 per cent sulphuric acid. An analogous reversion to olefin is more likely to occur in the recovery of higher secondary and tertiary alcohols. It is sometimes found advantageous to carry out hydrolysis for a considerable period prior to distillation,[41] but this does not appear to be the usual practice.

The general procedure employed in the manufacture of isopropyl alcohol, after absorption of the olefin in acid, is as follows: (1) dilution of the reaction mixture with sufficient water to reduce its acidity below 50 per cent (in most instances to about 35 per cent) and (2) immediate distillation to secure a constant-boiling mixture of alcohol and water as an overhead product. Residual acid may then be reconcentrated and employed in the absorption stage.

---

[40] B. T. Brooks, *Ind. Eng. Chem.*, 1935, **27**, 278; *Brit. Chem. Abs.* **B**, 1935, 536; *Chem. Abs.*, 1935, **29**, 2700. *Proc. World Petroleum Congr.*, 1933, **2**, 840; *J. Inst. Pet. Tech.*, 1934, **20**, 105A.

[41] W. H. Groombridge and R. J. Peek, British P. 428,792, 1935, to British Celanese Ltd.; *Chem. Abs.*, 1935, **29**, 6901; *Brit. Chem. Abs.* **B**, 1935, 664.

Groombridge and Peek[42] propose to dilute acid liquor with about 5 moles of water to each mole of isopropanol virtually present. The solution is then fed into the top of a copper column packed with pumice and provided with a dephlegmator. The base of the column is heated to 130°C. In this manner the temperature at the top is maintained sufficiently high to effect hydrolysis of the esters and immediate distillation of the resulting alcohol (or ether). Concentration of the acid is said to be effected as it flows downward through the column. Wilson[43] recommends admixing bauxite during interaction of isopropyl sulphates and water, thus forming aluminum sulphate as a by-product. Alternatively, the metallic oxide may be added after hydrolysis and distillation have occurred. In the latter instance if any tarry material is present it should first be removed by heating at 175° to 200°C., so as to avoid contamination of the aluminum salt.

Another method comprises emulsifying acid solutions of dialkyl sulphates, at 70° to 80°C., with an equal weight of water and then distilling[44] the mixture. Higher temperatures may be employed in the first operation provided it is carried out under refluxing conditions.

DEHYDRATION OF ISOPROPYL ALCOHOL

The azeotrope of isopropyl alcohol and water (obtained by fractional distillation at atmospheric pressure) boils at 80.35°C. and contains 12.3 per cent (by weight) of water. Practically anhydrous alcohol can be recovered from this binary mixture by distilling in the presence of water-entraining agents, such as toluene, xylene, ethylene dichloride or benzine fractions.[45] As a method for extracting water from aqueous isopropyl alcohol, van Peski and Smithuysen[46] first carry out an azeotropic distillation of the solution, with benzene, benzine or ethyl chloride as entraining agent. The azeotropic mixture obtained is then extracted with a non-aqueous liquid: for this purpose kerosene, paraffinum liquidum or Edeleanu extract of spindle oil are available.

In other instances, solid drying agents, for example, anhydrous copper sulphate or calcium oxide, may be employed. Brooks[47] recommends contacting the liquid with a concentrated aqueous solution of sodium or potassium hydroxide or of calcium or zinc chloride.

Dehydration by any of these methods is said to be advantageous when followed by a final rectification which effectively separates the alcohol from ill-smelling polymers.[48] Incidentally, the latter compounds may be extracted from acid liquor (before or after hydrolysis) by the same solvents which are applicable in the azeotropic dehydration of isopropanol.[49]

Anhydrous gypsum, prepared by heating plaster of Paris or gypsum to 160-180°C. has been found effective for the vapor-phase dehydration of aqueous alcohol.[50] The inorganic salt is changed into a hemihydrate which can be subsequently reheated and reused.[51]

REFINING OF ISOPROPANOL

Tertiary butanol is often found as an impurity in isopropyl alcohol made from cracking gases. Its presence, even in relatively minute proportions, can be readily detected by heating the specimen (under examination) with a sulphuric acid solution of mercuric sulphate for 20 to 30 minutes on a water bath. The formation of a yellow precipitate (or discoloration) is characteristic of tertiary alcohols.[52]

For the removal of tertiary butanol (and other analogous alcohols) from secondary alcohols, advantage may be taken of the ease of anhydration of the former under the influence of dilute acids. Thus, Buc[53] suggests heating crude isopropyl alcohol with concentrated sulphuric acid (sp. gr. 1.84) that has been diluted with an equal volume of water. For example, 200 cc. of diluted acid are added to 1000 cc. of alcohol and the mixture heated to boiling temperature, under reflux on a water bath, for about 48 hours. The product will be found to contain only traces of tertiary impurities, say about 0.05 per cent, in a material carrying 3 per cent originally. For a higher degree of purity the heating may be continued 24 hours longer.

During the purification, some isopropanol, up to 10 per cent, may be lost by conversion to propene. It is recommended that the concentration of the acid be reduced by the addition of more water, before separating the refined product by fractional distillation of the acid liquor. The treatment may be carried out more rapidly with acid of higher concentration, but the losses of isopropanol will be greater and a certain amount of polymerization may be expected. A similar purification, recommended by Lebo,[54] comprises warming the alcoholic mixture (at temperatures not above 40°C.) with 20 per cent sulphuric acid and a compound of vanadium, aluminum or copper. Olefinic hydrocarbons produced during this operation are continuously recovered. They may be converted again into tertiary alcohols by absorption in sulphuric acid followed by hydrolysis and distillation.

Merley[55] suggests passing alcohol vapors, at 95° to 97°C., countercurrent to a stream of dilute sulphuric acid (about 25 per cent concentration) to effect elimination of easily decomposable alcohols and also of sulphur compounds. Another procedure for removal of the latter comprises treatment with an aqueous solution of sodium plumbite.[56] Afterwards the alcohol is subjected to rectification and fractionation.

Technical isopropanol may sometimes contain a small proportion of oily polymers which cause a turbidity on dilution with water. The cloudiness is first noticeable with 0.6 per cent of the latter liquid. Refining may be accomplished, according to Rudakova,[57] by treating with petroleum ether, calcium hydroxide, and sodium chloride, followed by filtration through charcoal.

Chapter 15

Properties and Uses of Isopropyl Alcohol and Its Derivatives

Details of the preparation of isopropyl alcohol from propene by the sulphation process have been given in the previous chapter. Separation of the resulting alcohol from impurities, such as tertiary butyl alcohol and oily polymers, was also discussed. The following account of the properties of pure isopropyl alcohol and of its numerous applications in industrial and scientific work is intended to supplement that already provided in the previous volume.[1]

PHYSICAL PROPERTIES OF ISOPROPYL ALCOHOL

Some data relating to various physical constants of pure anhydrous isopropyl alcohol are summarized in Table 83.

TABLE 83.—*Physical Properties and Constants of Isopropyl Alcohol.*[2]

Melting point	-85.8°C.
Boiling point	82.4°C. at 760 mm.; $dt/dp = 0.033$°C. per mm.
Vapor pressure	32.4 mm. of Hg. at 20°C.
Density	$d_4^{20} = 0.7887$ (0.7283 at boiling point)
Flash point (closed cup)	11.7°C. or 53°F.
Refractive index (n_D)	1.37925 at 15°C.; 1.37757 at 20°C., 1.3749 at 25°C.
Critical temperature	234.9°C.
Critical pressure	53 atmospheres.
Latent heat of vaporization (at 82.4°C.)	160 cal. per gm.
Heat of combustion	7970 cal. per gm.; 474.8 kg.-cal. per mole
Sheafer heat (cal. per gm. per °C.)	0.563 at 0°C.; 0.677 at 30°C.; 0.740 at 50°C.
Surface tension	21.7 dynes per cm. at 20°C.
Dielectric constant	26 at 20°C.
Electrical conductivity	35×10^{-7} reciprocal ohms at 25°C.
Heat of fusion	21.08 cal. per gm. at melting point.
Vapor density	2.127 at 100°C.
Heat conductivity	3.683×10^{-4} c.g.s. units at 0°C.

The variation of surface tension of isopropyl alcohol against its vapor (mixed with air) is shown in Table 84.[2a]

TABLE 84.—*Surface Tension of Isopropyl Alcohol Against Its Vapor.*

Temp., °C.	Surface Tensions (dynes per cm.)
5	22.8
20	21.7
50	19.3
80	17.0

Isopropyl alcohol forms a constant-boiling mixture with water, containing 91.1 per cent by volume of the alcohol (87.7 per cent by weight) and boiling at 80.4°C. under 760 mm. pressure. This binary azeotrope has the following physical constants: d_4^{20}, 0.8158; $d_{60°F}^{80°F}$ 0.8190; N_D^{20} 1.3765; viscosity, 0.02106 poise at 25°C.; closed flash point, 64°F.; and coefficient of expansion, 0.001062 per °C.

The free energy of hydration of a number of alcohols, including isopropyl alcohol, has been calculated by Butler, Ramchandani and Thomson[16] from their experi-

mental measurements of the vapor pressures of these alcohols in dilute aqueous solutions at 25°C.

Isopropyl alcohol forms a large number of constant-boiling binary mixtures with other organic compounds, some of which are listed in Table 89.[17]

Several ternary constant-boiling mixtures containing isopropyl alcohol are known. Thus water, benzene and the alcohol form a composition boiling at 66.5°C. and containing 18.6 per cent moles of alcohol and 56.5 per cent moles of benzene. A combination of 52.7 per cent moles of cyclohexane, 21.8 per cent moles of alcohol and 25.5 per cent moles of water has a boiling point of 66.1°C. Another fluid containing 54.8 per cent moles of cyclohexane, 19.2 per cent moles of isopropyl alcohol and 26.0 per cent moles of water, has a constant boiling point, at normal pressure, of 64.3°C.

The physical characteristics of a number of binary mixtures containing isopropyl alcohol as one component have been recorded. These include mixtures of the alcohol with acetone,[17a] ethyl alcohol,[18] acetaldehyde or heptaldehyde,[19] and benzene.[20] Olsen and Washburn[21] have determined freezing point data for solutions of isopropyl alcohol in benzene and also the equilibrium concentrations of the ternary system, isopropyl alcohol-water-benzene, at 25°C., as well as the viscosities of equilibrium mixtures of these three components. See Table 90.

Isopropyl alcohol, when added to gasoline-ethyl alcohol mixtures, brings about a marked increase in the critical water content, i.e., in the water tolerance of such mixtures.

Bayley and Hopkins[22] found that replacement of half the ethanol content of an ethyl alcohol-gasoline blend by isopropanol caused an increase in water tolerance of about 60 per cent at —80°C. and almost 100 per cent at —40°C. This effect is illustrated by the results shown in Table 91. The gasoline in the tests was a commercial motor fuel and did not contain tetraethyl lead. The diluents were dehydrated materials. Benzene is included for comparison.

Like other alcohols, isopropanol cannot be mixed with calcium chloride since it forms an addition compound with that reagent. A complex compound with zinc chloride has also been reported.[23] The solubility of a number of inorganic salts, including magnesium bromide and iodide,[24] in isopropyl alcohol has been recorded.

Ferner and Mellon[25] reported data for the solubilities of sodium and potassium chlorides at 16°-35°C. in absolute isopropanol and in aqueous mixtures containing 87.7, 92.6 and 96.5 per cent of this alcohol. The solubilities of calcium, barium and strontium as nitrates at 25°C. in anhydrous isopropyl alcohol were also determined.

Solubilities of the alkali chlorides and sulphates in anhydrous isopropyl alcohol have been measured by Kirn and Dunlap.[26] Anhydrous potassium sulphate was insoluble. Solubilities of the chlorides of both sodium and potassium and the sulphate of the former pass through a maximum solubility with increase in temperature and then decrease. According to Hopkins and Quill,[27] isopropyl alcohol is a very poor solvent for the rare earth chlorides. Neuman[28] determined the solubility of silver bromate in mixtures of isopropyl alcohol and water.

ANALYTICAL REACTIONS OF ISOPROPYL ALCOHOL

The most satisfactory method of detecting and estimating isopropyl alcohol in mixtures consists in oxidation with a sulphuric acid solution of chromic acid followed by distillation and identification of the resulting acetone, which can be also readily estimated volumetrically.[29] Solutions of isopropyl alcohol in water or other non-oxidizable solvents may be quantitatively estimated[30] by chromic acid oxidation. Substitution of the latter by permanganate yields acetone and other products, including carbon dioxide, oxalic acid and acetic acid,[31] so that this reagent is not readily applicable to the quantitative estimation of isopropyl alcohol.

The xanthate-iodine titration method yields quantitative results in the case of isopropyl alcohol and is also applicable to the determination of other primary and secondary alcohols,[32] provided only one alcohol is present.

According to Brown,[33] a solution of isopropyl alcohol containing 1 per cent vanillin gives a Prussian-blue coloration when treated with 1 to 3 per cent of concentrated sulphuric acid. Different, but distinctive, colorations are exhibited by methyl or ethyl alcohol but amyl alcohol also gives a Prussian-blue color under these conditions. In the absence of other color-producing substances, 1 part in 10,000 of isopropyl alcohol can be detected by this test in mixtures containing it. The manner of conducting the test may be described as follows: Dissolve 0.1 gram vanillin in 10 cc. of the alcohol and allow 1 cc. concentrated sulphuric acid to run down the side of the test tube. With isopropanol, the zone is red below, deep blue above and the mixture is similar to Prussian blue. With amyl alcohol, the zone is dull red below, deep blue above, the mixture is blue and a white precipitate is formed. To differentiate between these two alcohols, add 10 cc. water to each mixture and shake. With isopropanol, the pale blue mixture rapidly turns colorless; with the amyl compound, a grass-green alcoholic upper layer is permanent, even after 2 hours; also a white deposit settles in the colorless aqueous lower layer.

For taxation purposes in India, the term "spirit" includes methyl, ethyl, propyl and isopropyl alcohols. It was found by Aiyar and Krishman[34] that, for the determination of alcohol in mixtures containing isopropanol, the Thorpe and Holmes[35] method failed to give the true alcoholic content. The following modification of the usual procedure was developed by Aiyar and Krishman, to be used with mixtures thought to contain isopropyl alcohol:

To 100 cc. of liquid containing around 30 per cent of "spirit" add common salt to the saturation point. Agitate with 50 cc. petroleum ether (B.P. 40-60°C.) and allow to settle. After drawing off the brine layer, wash the ether extract first with 10 cc. of saturated brine and then with 5 portions of water, combining all these washings with the first salty extract. Collect the first 100 cc. that passes over on distilling the total brine liquor and determine isopropyl alcohol content by specific gravity

Although a sulphuric acid solution of mercuric sulphate (Denigès' reagent) has been suggested as a reagent for the detection of isopropyl alcohol, it has been shown that pure isopropanol gives an entirely negative test and that the yellow precipitate, or coloration, often obtained, is due to impurities in the isopropyl alcohol tested.[36] The most common impurity is tertiary butyl alcohol, which gives an immediate reaction with Denigès' reagent. According to Pukirev,[37] the tertiary butyl alcohol content of isopropyl alcohol is conveniently estimated by comparing the turbidity, or opalescence, obtained by adding 3 cc. of the Denigès' reagent[38] to 0.1 cc. of the isopropyl alcohol solution, with a series of standard solutions. The method is not applicable to concentrations of tertiary butyl alcohol below 0.5 mg. per liter.

[33] C. L. M. Brown, *Pharm. J.*, 1934, **133**, 560; *Brit. Chem. Abs.* **B**, 1935, 137; *Chem. Abs.*, 1935, **29**, 2111.

[34] S. S. Aiyar and P. S. Krishman, *Analyst*, 1935, **60**, 237; *Brit. Chem. Abs.* **B**, 1935, 539; *Chem. Abs.*, 1935, **29**, 3628.

[35] T. E. Thorpe and J. Holmes, *Trans. Chem. Soc.*, 1903, **83**, 314; *J.S.C.I.*, 1903, **22**, 314. This method of analysis is based on the fact that the alcohol in 25 cc. of strong spirit, even when diluted to the extent of 500 cc., can be entirely recovered by distillation, provided the solution is first saturated with common salt. The original alcohol may then be regained in the first 100 cc. of the distillate.

Buc[39] describes the testing of isopropanol for tertiary butanol by use of Denigès' reagent.[40] The method consists in heating on a water bath for 20 to 30 minutes a mixture of about 10 cc. of an acidified mercuric sulphate solution with about 0.2 cc. of the isopropyl alcohol. If tertiary alcohols are present, a yellow precipitate is formed. The color is distinctive in case of even a few hundredths of one per cent of the impurity. In absence of the trimethyl carbinol, the precipitate is white or only slightly yellowish.

ISOPROPOXIDES

Alkoxides of aluminum have been found to be effective agents[41] for the reduction of aldehydes to the corresponding alcohols. An example of such is the transformation of crotonaldehyde to crotyl alcohol. Acetone is a by-product of these reactions though its removal as fast as formed leads to increased yields of alcohol. Satisfactory production of the alcohol resulted from the employment of benzene (40-45 per cent) and isopropyl alcohol (58-60 per cent) as reacting media. The latter solvent not only gave higher yields but was more convenient, since the propoxide could be prepared in the reaction flask and immediately used without separation and purification.

The aluminum alkoxide gave a 32 per cent yield of citronellol from citronellal and a 68 per cent production of cinnamyl alcohol from cinnamaldehyde.

The investigators made the metallic alkoxide from aluminum amalgam and isopropyl alcohol by a modification of the Adkins method.[42]

Aluminum wire or turnings (100 grams), absolute isopropyl alcohol (1200 cc.) and mercuric chloride (5 grams) are placed in a 2-liter round bottomed flask provided with a reflux condenser. By means of a steam bath, the mixture is gently warmed for 10 or 20 minutes until a gray precipitate is formed. The reaction then becomes so vigorous that external cooling is necessary until this activity ceases. Heating and refluxing is then continued for 6 or 7 hours. The aluminum isopropoxide may then be used for the aldehyde-alcohol reaction described above, or purified by distillation. The yield with the above amounts specified is 645-680 grams (85-90 per cent) of alkoxide, with a boiling point of 145-150°C. (5 mm.).

The aluminum isopropoxide was found in every instance superior to the ethoxides of the same metal or of chloromagnesium for carrying out aldehyde reductions similar to those described above.

INDUSTRIAL APPLICATIONS OF ISOPROPYL ALCOHOL

In addition to its utilization on a comparatively large scale for the production of various chemical products (see below), the main industrial applications of this alcohol are based on its solvent properties for a wide variety of materials. It finds extensive use in the preparation of perfumes, odorants, plant extracts and medicinal products for external use. Although unsuitable, pharmacologically, for internal medication and as a component of mouth washes, this alcohol can be employed advantageously in the preparation of various cosmetics. Vapon, used as a hair wash or shampoo fluid, contains a high percentage of isopropyl alcohol.[43]

Pharmacology. Isopropanol has been accepted for admission to the approved list of New and Non-official Remedies by the U. S. Council of Pharmacy and Chemistry.[44] The alcohol may be used for the removal of creosote from the skin as a prophylactic agent against creosote burns.[45] It is also recommended for disinfection of the skin and of hypodermic syringes and needles. It may be employed as a disinfecting agent in the administration of insulin. However, the alcohol cannot be relied upon to destroy such spore-forming organisms as *Clostridium tetan*, *Clostridium welchii* or *Bacillus anthracis*. Isopropanol for uses noted above must conform with three tests, *viz.*,

Total solids. Not more than 0.01 per cent residue is allowable after drying, at 100°C., the material obtained by evaporation of 100 cc. of the alcohol in a platinum dish on a water bath.

Aldehyde. Treat 20 cc. of the alcohol with 1 cc. of freshly prepared ammonio-silver nitrate solution by shaking thoroughly in a stoppered test-tube and allowing to stand for at least six hours in diffused daylight. No more than a faint cloudiness or tinge of brownish color is tolerated.

Acetone should be absent. If present, a purplish red color is obtained by the following procedure. Mix thoroughly 5 cc. alcohol, 2 cc. of 1*N* sodium hydroxide solution and 5 drops of a 1 per cent sodium nitroprusside solution; then acidify carefully with acetic acid.

According to Westermann,[46] isopropyl alcohol has a higher disinfecting value than ethyl alcohol, a 50 per cent solution of the former having about the same power as a 70 per cent solution of the latter. For sterilization of the hands, a 30 per cent solution of isopropyl alcohol, containing 1 per cent of the soap preparation known as Baktol, is very efficient, having no unpleasant odor and no injurious action on the skin.

For the stabilization of egg material to be used in shampoo mixtures, isopropyl alcohol and other monohydric alcohols are added in a proportion of 7.5 to 20 per cent of the water present in the finished product.[47]

Isopropanol has been proposed as a precipitating agent for the elimination of asphalt from petroleum oils.[48] For this purpose the alcohol should be practically anhydrous. Similarly, the dewaxing of lubricating oils may be accomplished by treatment with *sec*-butyl acetate that contains 10-25 per cent by volume of isopropyl alcohol.[49] The mixture should be chilled to precipitate the wax.

Isopropyl alcohol and secondary butyl alcohol have been suggested as effective in the separation of sulphonates from the acid sludge obtained by sulphuric acid treatment of hydrocarbons. The sludge is washed with water, neutralized and then extracted with the solvent. Separation takes place into three portions: namely, a tarry material, a solution of inorganic salts and a third layer containing a solution of sulphonates in the solvent.[50]

Isopropanol as a Non-Solvent in Rubber Cements. A systematic study of the effects of a number of non-solvents on rubber cements has been made by Ford.[51] The use of ethyl alcohol for reducing the apparent viscosity of such compositions is an established practice, though acetone and amyl acetate are known to function in the same manner. The experiments reported were concerned with the control of film-thickness on dipped articles and the tendency of wet films to break across small holes in perforated objects. The commercial benzene cement utilized for the trials originally contained 250 grams of non-volatile ingredients per liter of finished product. The addition of non-solvents to the cement improved the film-breaking tendency. The various liquids tested for this purpose could be arranged in the following order of decreasing effectiveness: isopropanol, ethanol, Pentasol (technical), butanol (technical), amyl and butyl acetates, acetone, methyl ethyl ketone and benzene. Volume for volume there was no difference in this respect between the first two alcohols named, but more than 10 per cent of ethanol caused coagulation, while over 15 per cent of isopropanol could be present without such coalescence occurring. In deposited films wide variations in alcohol content due to evaporation of benzene-ethanol mixtures tend to irregular breaking of films but this trouble is eliminated by the use of isopropanol. The maximum film-breaking effect resulted on use of cements containing about 11 per cent (by volume) of isopropyl alcohol. This addition resulted, however, in reduction of film thickness, which could be offset by a longer mastication period for the rubber stock and a variation of non-volatile ingredients. It was found that below about 33 per cent (by volume), isopropanol is not completely dissolved in benzene. This same ratio was shown to exist beween isopropanol and total solvent just where coagulation of the cement occurred. About 50 parts of isopropyl alcohol to 100 parts benzene were necessary for the formation of a clear solution. In the wet cement film Ford considered the isopropanol to exist in a state of very fine dispersion.

Anti-Freeze Mixtures. An important commercial application of isopropyl alcohol is in the preparation of anti-freeze compositions for automobile radiators. For this purpose a 65:35 blend of isopropyl and methyl alcohols is being marketed.[52] The mixture is reported to be superior to ethyl alcohol for this purpose since, on dilution with water, it does not attack metal parts, rubber or varnishes.[53] A similar anti-freeze composition disclosed by Howard[54] consists of 75 to 55 per cent by volume of isopropanol with 25 to 45 per cent methyl alcohol. When diluted with water, this mixture is said to duplicate substantially the density, volatility and freezing point of an aqueous solution containing an equivalent proportion of ethyl alcohol.

The addition of a small quantity of a petroleum distillate of density greater than 0.8 and boiling point higher than 300°C., to anti-freeze compositions of this type is proposed for detecting their dilution. The mixture becomes milky on addition of less than 5 per cent of water.[55]

Berliner[56] states that anti-freeze compositions containing aliphatic alcohols may be rendered non-corrosive by the addition of a small proportion (0.1-0.5 per cent) of an alkyl (or aryl-) antimonyl tartrate. Amino-derivatives of these compounds are also effective for this purpose.

Some investigations seem to indicate that isopropyl alcohol may find application in gasoline mixtures for use as motor fuels. Thus, as previously mentioned, Bayley and Hopkins[57] show that addition of isopropyl alcohol to gasoline-ethyl alcohol mixtures results in a marked increase in the critical water content of such compositions. Ormandy, Pond and Davies[58] studied the blending behavior of isopropyl, *n*-butyl, isobutyl and tertiary butyl alcohols with a typical gasoline and with certain motor fuel hydrocarbons. They concluded that isopropyl alcohol had the best all-round mixing properties of any of the above named substances.

Another possible application of isopropyl alcohol is as an agent for removing ice from airplane carburetors.[59]

Isopropanol as a Solvent. On account of its cheapness and freedom from tax restrictions, isopropyl alcohol is now being used extensively in chemical analysis in place of ethanol which is not only more costly but often inconvenient on account of the precautions necessary to prevent its illicit diversion. The applications in analytical chemistry have been reviewed by Ferner and Mellon,[60] who found that it was an effective solvent in a number of analytical tests, for example, in preparing solutions of dimethylglyoxime, 8-hydroxyquinoline and alpha-benzoinoxime. Schuette and Harris[61] used isopropyl alcohol as a solvent for potassium hydroxide. Ferner and Mellon found that $0.1N$ solutions were stable but $0.5N$ solutions developed a color even in the dark.[62] Isopropanol may replace ethanol in the qualitative test for chromates involving reduction to green tervalent chromium. However, it proved unsatisfactory as a substitute in the flame test for borates and in the acetate test given by the U. S. Pharmacopeia. Several examples of the use of isopropyl alcohol in the separation of inorganic salts have been given by Ferner and Mellon. Included were the separation of calcium nitrate from barium nitrate, of calcium oxide from magnesium oxide and of alkali chlorides from magnesium chloride.

CHEMICAL DERIVATIVES OF ISOPROPYL ALCOHOL

Acetone. The production of acetone from isopropyl alcohol by catalytic dehydrogenation is now carried out commercially on a large scale.[63] In addition to acetone, a number of other derivatives of isopropyl alcohol, including various esters, diisopropyl ether and isopropyl phenols, are finding important applications in industry.

Esters of Isopropyl Alcohol. Table 92 summarizes the physical constants of a number of isopropyl esters of organic and inorganic acids.

Organic Esters. Isopropyl esters of organic acids are usually prepared by direct interaction of the alcohol carboxylic acid in the presence of a condensing agent, such as sulphuric acid. They may, however, be obtained directly from

propene by treatment with organic acids in the presence of catalysts or from isopropyl sulphate liquors by reaction with the corresponding acids.[65]

Nazarov and Khain[66] consider petroleum sulphonic acid to be a more effective condensing agent for isopropanol and acetic acid than sulphuric acid. The highest yield of isopropyl acetate was 94 per cent of the original acetic acid treated. The reactants were mixed in the ratio of 4.22 parts of alcohol to one of acid. The temperature was 105-110°C. and the feed rate 1 cc. per min. With technical products the proportions of alcohol and acid would be 5.2:1 in which case the yields would be 42 per cent based on the anhydrous acid or 58 per cent, on the commercial acetic acid. No gases or polymers were formed and there was no dehydration of the alcohol which was reported to be 98 per cent converted. Of the petroleum sulphonic acids, approximately 8.2 grams sufficed for the production of one kg. of isopropyl acetate. Even then the catalyst was only slightly weakened. Dried catalysts and the technical form were equally effective. Nazarov and Khain call attention to the cheapness of the petroleum sulphonic acids in comparison with sulphuric acid, generally used.

Boron trifluoride is likewise a catalyst both for the esterification of isopropyl alcohol and for the direct condensation of propene and organic acids.[67] For example, yields of 16.8, 38.8, 48.6, 57.8 and 60 per cent, respectively, of the corresponding isopropyl esters were obtained from acetic, mono, di-, trichloroacetic and benzoic acids by treatment with isopropanol and boron trifluoride. Equimolar proportions of each acetic acid and the alcohol were refluxed for three hours with 3 g. of boron trifluoride per mole of acid. Equal weights of benzoic acid and the alcohol were under reflux for 50 minutes. When a solvent or suspension medium (such as carbon tetrachloride) was incorporated with the chloroacetic acid and the mixture agitated, complete esterification took place in one hour.

It is of interest that these workers obtained the same esters in yields of 7.0, 34.2, 39.5, 48.8 and 88.0 per cent, respectively, by combination in turn of the acids mentioned above, with propene in presence of boron trifluoride. Addition took place at 70°C. under a pressure of about 25 cm. of mercury above atmospheric.

---

[64] Data from International Critical Tables, McGraw-Hill Book Co., Inc., New York, 1926.

[65] The direct esterification of olefins is discussed in Chapter 12.

[66] S. A. Nazarov and S. S. Khain, *Mat. on Cracking*, 1935, No. 2, 183; *Brit. Chem. Abs.* **B**, 1936, 631; *Chem. Abs.*, 1935, **29**, 6032.

[67] T. B. Dorris, F. J. Sowa and J. A. Nieuwland, *J.A.C.S.*, 1934, **56**, 2689; *Brit. Chem. Abs.* **A**, 1935, 195; *Chem. Abs.*, 1935, **29**, 724.

Attention was called, by these investigators, to the fact that Sudborough and Lloyd[68] reported results which were in the reverse order on using hydrochloric acid to catalyze the same esterifications with isopropyl alcohol as those reported above.

Isopropyl acetate has been obtained by Sowa and Nieuwland[69] on interaction of isopropyl with the addition compound of acetamide and boron trifluoride. The yield seemed to depend on the amount of the fluoride used, so long as an excess of the addition compound was avoided. The methathesis which took place is indicated by the equation

$$CH_3CONH_2 \cdot BF_3 + (CH_3)_2CHOH \longrightarrow CH_3COOCH(CH_3)_2 + BF_3 \cdot NH_3$$

Formation of the amino boron fluoride was considered to be the "driving force" of the reaction. The acetamide-boron fluoride addition was accomplished by passing one mole of the metallic fluoride into a 500 cc. flask containing one mole of acetamide. On introduction of one mole of isopropyl alcohol the amino boron fluoride soon separated as a white solid. After refluxing the mixture for about half an hour, the isopropyl acetate could be distilled directly from the reaction vessel through a fractionating column. A 32 per cent yield was obtained. Analysis of the solid residue showed it to contain one mole of ammonia. Practically all the boron fluoride could be recovered by heating the residue, after removal of organic matter, with concentrated sulphuric acid.

This and similar esters may also be produced by reacting diisopropyl ether with the required aliphatic monocarboxylic acid in the presence of catalytic proportions of a strong non-volatile acid, such as sulphuric. The process is most successful when carried out by heating under pressure.[70] For instance, diisopropyl ether and acetic acid, when heated to about 120°C., furnish isopropyl acetate if 2 to 4 per cent sulphuric acid is included as a condensing agent.

Merley[71] proposes rectification in the absence of water to remove impurities. such as hydrocarbons and mercaptans, from esters. The latter is then redistilled (to eliminate entrained material) with a constant proportion of water at substantially atmospheric pressure. The purification is completed by drying the ester.

Secondary alkyl esters of polycarboxylic acids of relatively high boiling point, such as isopropyl phthalate, have been recommended[72] as heat-transmitting agents. Isopropyl esters of the acids obtained by oxidizing paraffin wax, are suggested as components of a rinsing oil for motors.[73]

Isopropyl bromide may be produced in the laboratory by heating isopropyl alcohol with potassium bromide and sulphuric acid. It has been shown by Werner[74] that considerable amounts of propene are formed when using concentrated acid for this reaction, in which case poor yields (38 per cent) of ester are obtained. The formation of olefin can be suppressed by dilution with at least 10 per cent of water. On heating 100 g. of a 3:1 molar mixture of isopropanol and water, 150 g. concentrated sulphuric acid and 210 g. of sodium bromide dihydrate to 90°-115°C., a 73.5 per cent yield of isopropyl bromide resulted, without olefin production.

The rate of hydrolysis of isopropyl bromide in alkaline media is unimolecular in very low hydroxyl ion concentrations (e.g., 0.005*N* sodium hydroxide) but at higher concentrations (for example, 0.1*N* sodium hydroxide), a bimolecular substitution reaction takes place accompanied by elimination of propene as a second-order reaction.[75]

Sodium isopropyl xanthate is reported as having a number of uses commercially, e.g., as accelerator in rubber vulcanization, in the preparation of insecticides and in flotation processes.[76]

ISOPROPYL ETHER

Isopropyl ether is rapidly assuming a role of importance in chemical industry. Next to acetone, it may prove the most valuable commercially of the derivatives of isopropanol. It is obtained as a by-product in the manufacture of isopropyl alcohol by the acid absorption process, whenever substantial proportions of diisopropyl sulphate are present in the reaction liquor.

A distillation process for the separation of mixtures of isopropyl ether and isopropanol has been described.[77] Enough water is maintained in the liquor to give a constant boiling minimum mixture, in this case 9 parts of isopropyl ether to 1 part of water, (b.p. 73-74°C.). Addition or return of water is stopped in time to avoid carrying over isopropyl alcohol which remains in the still.

Another procedure for preparing the ether involves treatment of propene, under pressures of 3.5 to 35 kg. per sq. cm., with 70-85 per cent sulphuric acid at temperatures up to 50°C.[78] The product may then be recovered by reducing the pressure to 1 atmosphere (*ca.* 1 kg. per sq. cm.) and increasing the temperature to 100-125°C. However, isopropyl ether is often made by dehydration of the corresponding alcohol under the influence of sulphuric acid. Brik[79] has described a continuous process utilizing this reaction by heating 100 parts of isopropyl alcohol with 37.5 parts of 100 per cent sulphuric acid. A yield of 43.5 per cent was secured and the ether could be separated from the distillation product by three successive washings with 2 volumes of water.

Physical Data for Isopropyl Ether. The physical characteristics of this compound are summarized[80] in Table 93.

TABLE 93.—*Physical Constants of Isopropyl Ether.*

Boiling point at 760 mm.	153-158°F. (67-70°C.)

Propyl isopropyl	—	—	—	65	81
Butyl isopropyl	—	—	—	62	83

Both ethyl and *n*-propyl ether were unaffected by equal volumes of concentrated sulphuric acid. The other ethers tested were subject to slow decomposition by such treatment, the isopropyl being attacked at the same rate as the mixed ethers. After 5 cc. of 92 per cent sulphuric acid had reacted with 4 cc. of isopropyl ether for 3 days, only 1.1 cc. of the latter could be recovered.

Because of the action of sulphuric acid noted above, some details of methods for preparing other alkyl ethers are of especial interest. For example, studies[82] of the equilibrium between dimethyl ether, methanol and water, using a potassium-alum catalyst, indicated an 88.7 per cent conversion of anhydrous alcohol to ether at 230°C. A 99.3 per cent yield was possible with sulphuric acid as activator at 130°C., but above this point dimethyl sulphate was formed. Dehydration of normal propyl alcohol in vapor phase by means of potassium-alum showed a maximum, 84 per cent, conversion to normal propyl ether at 190°C. It has been noted that propyl ether is more stable at 230° than the corresponding alcohol.[83] This is considered an indication that the normal ether cannot be the intermediate product when propene is made by dehydration of propyl alcohol.

USES OF ISOPROPYL ETHER

Solvent. Isopropyl ether may be employed industrially in solvent extraction operations. Thus, Reid[84] has disclosed the use of this ether, alone or in admixture with other solvents, for the precipitation of wax from petroleum oils. For example, 30 gallons of wax distillate were dissolved in a mixture of 60 gallons of isopropyl ether and 40 gallons of acetone After cooling the solution to 0°C., the precipitated wax was filtered off, washed with a small amount of solvent and dried. The lubricating oil recovered after distillation of the solvent had a pour point near 0°C.

Govers[85] has found a combination of 3 parts isopropyl ether and 2 parts aniline to have a selective action, at low temperatures, on the liquid hydrocarbons of wax-bearing mineral oils. The viscous raw material is incorporated with the solvent and cooled to about −18°C. After removing the precipitated waxes, most of the ether is vaporized from the dewaxed liquid. A second extraction is then carried out with aniline alone. The resultant mixture, at about 15°C., can be divided into extract and raffinate phases. By removal of solvent from the latter, a low-pour-test lubricating oil of high viscosity is obtained.

Carruthers[86] recommends isopropyl ether for the extraction of dialkyl sulphates from acid liquors resulting from absorption of olefins in recovered acid containing carbonaceous polymerization products.

Before cooling hydrocarbon oils to cause deposition of wax, Sullivan[87] proposes to add a diluent consisting of methyl acetate, 30 parts, and isopropyl ether, 70 parts.

Other uses for this ether are as a solvent,[88] either alone or admixed with ethyl acetate,[89] in the extraction (from dilute aqueous solutions) of aliphatic acids (e.g., acetic), as a precipitating medium (for molding powders made from cellulose acetate) when admixed with acetic acid,[89a] and as an ingredient (to the extent of 1 to 5 per cent) of a cleaning solution of which the other components consist of 85 per cent of a mixture of phosphoric acid, ethyl alcohol and water.[90] The latter composition is said to be effective in the prevention of rust on materials made of iron.

Isopropyl Ether a High-octane Blending Agent. The discovery has been made that isopropyl ether, unlike ethyl ether, possesses high anti-detonating properties when mixed with gasoline. This ether thus becomes of value as a supplementary material to isooctane in the production of high-octane motor fuels, particularly aviation gasolines. According to Buc and Aldrin,[91] a mixture of 60 per cent aviation gasoline (octane number about 74) and 40 per cent isopropyl ether has an octane number of 100 when only 3 cc. of tetraethyl lead per gallon are added. This blend has a minimum specific fuel consumption 5 to 7 per cent higher under cruising conditions than the usual 100-octane isooctane blend while the power outputs and consumptions under high-power conditions are similar. The blending value of isopropyl ether is said to be slightly better than that of technical isooctane irrespective of the presence or absence of lead tetraethyl in the fuel under investigation.

UNSTABLE PEROXIDES FROM ETHERS

The tendency of ethers to form unstable peroxides has been emphasized by a number of investigations. In 1933, Robertson[92] stated that an explosion had taken place during distillation of some isopropyl ether. He noted the similarity of the circumstances and effects to those reported frequently with ethyl ether and attributed to the presence of peroxides.

In 1936, Morgan and Pickard[93] reported two violent explosions caused by accumulated peroxides in isopropyl ether. In one case, 100 cc. of ether that had been stored at least 4 years was being distilled on an electrically heated water bath. When the liquid did not seem to be boiling smoothly, the flask was gently shaken (assuming the liquid might be superheated) whereupon the explosion took place. Another sample of this ether gave peroxide reactions with acidified solutions of potassium iodide or permanganate and was found to contain large quantities of decomposition products.

Later, some diisopropyl ether had been used to remove small amounts of organic acids from an aqueous solution, and 50 cc. of the extract after drying, was being distilled over an electric heater. When about all the ether had distilled, a white fume appeared and the heat was switched off. An explosion followed shortly. This specimen of ether had been in stock 5 years and contained 8 per cent of higher boiling substances which gave the following tests for peroxides: (1) permanganate solution reduced to hydrated manganese dioxide, with liberation of oxygen; (2) mercury rapidly oxidized to a brownish black powder; (3) iodine liberated from aqueous potassium iodide. Morgan and Pickard advise testing all ether specimens of old or doubtful age for liberation of iodine from aqueous potassium iodide. In case peroxides are present, they may be safely removed by exhaustive treatment with either mercury or aqueous permanganate.

Williams[94] reports that practically all ethers formed peroxides on storage and that explosions have resulted in many instances when distillation of such liquids was attempted. He considers diethyl, diisopropyl, ethyl-*ter*-butyl, and ethyl-*ter*-amyl ethers may prove hazardous. Others, such as methyl-*ter*-butyl, methyl-*ter*-amyl or methyl-*ter*-hexyl, which may be distilled without appreciable danger, even after considerable storage periods are classed as less hazardous.[95] He recommends steam distillation, particularly in the presence of a small quantity of alkali, even though antitoxidants (e.g., α- or β-naphthol or hydroquinone) have been incorporated with the ether prior to storage.

The following procedure is given for the quantitative determination of peroxides in ethers:

To 150 cc. of $2N$ sulphuric acid and 10 cc. of the ether, add 3 to 5 drops of 1 per cent ammonium molybdate[96] solution followed by 15 cc. of 10 per cent potassium iodide solution. After shaking thoroughly, and allowing to stand for 15 minutes, titrate the liberated iodine with $0.05N$ sodium thiosulphate, shaking well after each addition of reagent. As the end point is approached, add a few cc. of starch solution as indicator and titrate to disappearance of the blue color.

Arup[97] advises that peroxides be decomposed by treatment of the ether with silver oxide. If this is not feasible then incorporation of a small proportion of a fatty acid or vegetable oil practically eliminates all danger. MacCulloch[98] recommends inclusion of a short length of copper wire in the amber-colored bottles employed for storage of anesthetic ether.

ISOPROPYL HYDROPEROXIDE

This compound has been prepared by Medvedev and Alekseeva[99] by treatment of diisopropyl sulphate with hydrogen peroxide (30 per cent) in the presence of potassium hydroxide. A 50 per cent yield was secured. The substance is a mobile liquid with an irritating odor, boiling at 107-109°C. and exploding if heated to a high temperature. It is miscible in all proportions with water, alcohol and ether. Although relatively stable in quartz vessels, as well as in neutral or acid aqueous solutions, it decomposes rapidly in alkaline solutions with the formation of acetone. If manganous salts are present, the peroxide is oxidized by acid permanganate solution. It liberates iodine from hydrogen iodide quantitatively. In dry ether, the peroxide does not affect hydroquinone but in moist ether (or water) oxidizes it to quinhydrone. Interaction with barium hydroxide produces salts that are relatively stable in the dry state in air freed from carbon dioxide. A compound of formula $(CH_3)_2CHO{\cdot}O{\cdot}BaOCO_2H{\cdot}3H_2O$ was isolated. Treatment with terephthalyl chloride converted the hydroperoxide into the di-peroxide ester, $C_6H_4(CO{\cdot}O{\cdot}OCH(CH_3)_2)_2$. This latter compound melts at 59°C., and explodes on further heating. It decolorizes indigo very slowly and does not affect potassium iodide solutions. In faintly acid or neutral aqueous solution it is slowly converted into terephthalic acid and acetone.

---

[94] E. C. Williams, *Chem. & Ind.*, 1936, 580; *Brit. Chem. Abs.* **A**, 1936, 1091.

[95] It has been pointed out that no explosions have been reported in the case of ethers boiling above 100°C., probably because the peroxides are slowly and safely decomposed at temperatures above the boiling point of water. See, *Ind. Eng. Chem., News Ed.*, 1936, **14**, 305.

[96] This substance acts as a catalyst for the liberation of iodine in the solution.

[97] P. S. Arup, *Chem. & Ind.*, 1936, 546; *Chem. Abs.*, 1936, **30**, 6563; *Brit. Chem. Abs.* **A**, 1936, 963.

[98] A. F. MacCulloch, *Chem. & Ind.*, 1936, 964.

The normal propyl hydroperoxide was not isolated in pure form, but was separated as the salt $CH_3CH_2CH_2O_2BaCO_3H{\cdot}3H_2O$. With both normal hydroperoxide and terephthalate, decomposition (with liberation of propionaldehyde) was much more marked than with the corresponding isopropyl derivatives.

ISOPROPYL ALCOHOL AS AN ISOPROPYLATING AGENT

Direct alkylation of aromatic hydrocarbons by means of isopropyl alcohol under the influence of sulphuric acid as catalyst has been known for some years and probably proceeds through the intermediate formation of isopropyl sulphate. This mode of operation is cheaper than the Friedel-Crafts' synthesis and, in some cases, yields substances isomeric with those furnished by the latter method. Condensation of isopropyl alcohol with benzene in the presence of concentrated sulphuric acid has been studied by Kirrmann and Graves[100] who obtained monoisopropylbenzene (cumene), *p*-diisopropylbenzene b.p. 210°C. at 760 mm., 1,3,4-triisopropylbenzene, b.p. 244° at 760 mm. and 1,2,4,5-tetraisopropylbenzene, m.p. 118°C. and b.p. 169°C. at 70 mm. Under similar conditions, toluene and the alcohol yielded *p*-cymene and diisopropyltoluene, b.p. 98°-100°C. at 14 mm. By treating toluene with isopropyl alcohol in 80 per cent sulphuric acid, Meyer and Bernhauer[101] secured a 35 per cent yield of cymene. Subsequently, Desseigne[102] pointed out that much cymene remained in solution in the sulphuric acid as a sulphonic acid, which could be steam distilled at 160°C. to bring the yield up to 82 per cent. In addition, about 14 per cent of 2,4-diisopropyltoluene and 2,4,6-triisopropyltoluene were formed. It is interesting to note that both *o*- and *p*-cymenes were produced in the above experiments. Desseigne also showed that when 95 per cent sulphuric acid was used as catalyst, the yield of cymene was reduced to 38 per cent and that of higher substituted products increased to 47 per cent. Interaction of isopropyl alcohol with *p*-nitrotoluene in the presence of sulphuric acid yielded 4-nitro-*o*-cymene and 4-nitro-2,6-diisopropyltoluene.

Condensation between secondary alcohols and aromatic hydrocarbons can also be brought about by aluminum chloride. According to Tzukervanik and Tokareva[103] an intermediate compound is formed between the metallic chloride and the alcohol, this complex subsequently undergoing reaction with the aromatic hydrocarbon according to the scheme:

[102] G. Desseigne. *Bull. soc. chim.*, 1935, (5) **2**, 617; *Brit. Chem. Abs.* **A**, 1935, 739; *Chem. Abs.*, 1935, **29**, 3995. *Compt. rend.*, 1935, **200**, 466; *Brit. Chem. Abs.* **A**, 1935, 612; *Chem. Abs.*, 1935, **29**, *2927*.

[103] J. Tzukervanik and K. Tokareva. *J. Gen. Chem.* (*U.S.S.R.*), 1935, **5**, 764; *Brit. Chem. Abs.* **A**, 1936, 61; *Chem. Abs.*, 1936, **30**, 442.

$$ROH + AlCl_3 \longrightarrow HCl + AlCl_2{\cdot}OR$$

and

$$AlCl_2{\cdot}OR + C_6H_6 \longrightarrow AlCl_2{\cdot}OH + R{\cdot}C_6H_5$$

From benzene and isopropyl alcohol in the presence of aluminum chloride, these investigators obtained mono- and di-isopropylbenzenes. Under similar conditions *p*-cymene was the main reaction product from toluene. Huston and Hsieh[104] condensed isopropyl alcohol with 2 to 5 equivalents of benzene in the presence of 0.5 equivalent of aluminum chloride and secured small quantities of mono- and polyisopropylbenzenes. No appreciable reaction was observed between phenols and isopropyl alcohol under similar conditions.

It is reported that phenols may be alkylated by secondary alcohols (such as isopropyl) using a zinc chloride catalyst.[105] The reaction is effected in the presence of a volatile liquid of boiling point lower than about 130°C., for secondary and tertiary alcohols, for which this method is especially suited. Solvent, phenol and alcohol are added to the dissolved zinc chloride. The mixture is then heated under reflux. After cooling, the upper layer (carrying the alkylated phenol) is washed with water to remove zinc chloride and purified by vacuum distillation. Addition of a small amount of a 1 per cent sodium hydroxide solution to the wash water has been found expedient in extracting the last traces of the catalyst.

The rearrangement of complex isopropyl aromatic ethers has been carried out by means of boron trifluoride.[106] For example, the addition of boron trifluoride gas to isopropyl phenyl ether, with no external cooling, resulted in a vigorous reaction. From 250 grams of the ether were obtained the following substances:

Phenols

2-isopropyl phenol	34 grams
2,4-diisopropyl phenol	44 "
2,4,6-triisopropyl phenol	28 "
phenol	90 "

Ethers

2-isopropylphenyl isopropyl ether	trace
2,4-diisopropylphenyl isopropyl ether	32 grams
2,4,6-triisopropylphenyl isopropyl ether	12 grams
phenylisopropyl ether	trace

Similar treatment of the isopropyl *o*-, *m*-, and *p*-cresyl ethers led to the generation of corresponding alkylated phenols or phenol ethers.

Conductivity measurements of the system phenol-boron fluoride indicated compound formation corresponding to $BF_3{\cdot}2C_6H_5OH$. A similar substance has been shown to result from an equimolar addition of boron fluoride to an alkyl phenyl ether. These intermediate reactions were considered by Sowa, Hinton and Nieuwland to explain the numerous inter- and intra-molecular changes reported. It was also stated that nearly all the compounds described in their work were likewise prepared from propene and the appropriate phenol.[107]

[107] For a discussion of the interaction between olefins and phenols, see Chapter 24.

Continuing this study of boron fluoride-organic reactions, Sowa, Hennion and Nieuwland[108] accomplished the alkylation of phenol with propyl alcohol. Identical compounds were obtained from both the normal and the iso-forms of propanol. No *n*-propyl phenyl ether was found in the products of reaction but only the derivatives containing the isopropyl radical (see Table 95.)

TABLE 95.—*Condensations of Propyl Alcohols with Phenol.*

Product	Yield in Grams per Mole of Phenol From Isopropyl Alcohol	 From *n*-Propyl Alcohol
2,4-Diisopropylphenyl isopropyl ether	11	13
2-Isopropyl phenol	28	32
4-Isopropyl phenol	20	16

Comparison of the physical properties of these substances showed them to be identical with those reported in previous work.[109] The results were considered to indicate that such condensations take place by means of intermediate-olefin formation followed by interaction with phenol.

Chapter 16

Production of Higher Secondary and Tertiary Alcohols. Reactions of Sulphuric Acid with Higher Homologues of Ethylene and Propene

The reaction between sulphuric acid and the higher monolefins differs in a real and important degree from that between this acid and the lower monolefins, e.g., propene or ethylene. This is technically important because of the difficulty in effecting separation (by fractional distillation) of isomeric olefins (e.g., butene and isobutene) or of olefins and the corresponding diolefins. Dilute sulphuric acid should be employed to reduce its polymerizing action, particularly on hydrocarbons of the isobutene type. Furthermore, if diolefins are present these may undergo considerable co-polymerization with monolefins, thus promoting undesirable side reactions rather than alcohol formation.

There are three general classes of higher olefins, each reacting with sulphuric acid in a different manner and at different reaction velocities.[1] These may be characterized as follows:

> Class I. The highly reactive tertiary olefins which contain the grouping:
>
> >
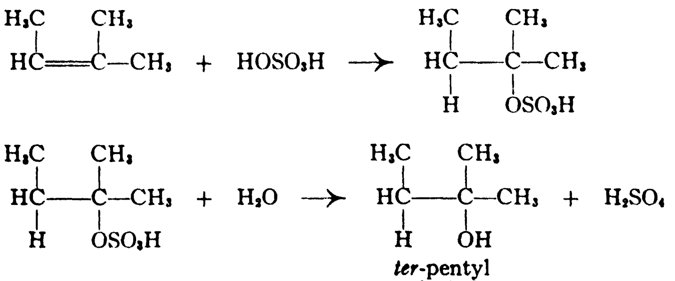
> $$R-\overset{H}{C}=\overset{R'}{C}-R''$$
>
> Where R′ and R″ are alkyl groups, and R represents an alkyl group or hydrogen atom. These compounds react and dissolve readily in sulphuric acid of 60 to 70 per cent concentration, but polymerize in the presence of acid of higher concentration. The product of sulphation and subsequent hydrolysis is a tertiary alcohol. Trimethylethylene is a typical example of this class of hydrocarbon:



$$\overset{H_3C}{HC}=\overset{CH_3}{C}-CH_3 + HOSO_3H \longrightarrow \underset{H}{\overset{H_3C}{HC}}-\underset{OSO_3H}{\overset{CH_3}{C}}-CH_3$$

$$\underset{H}{\overset{H_3C}{HC}}-\underset{OSO_3H}{\overset{CH_3}{C}}-CH_3 + H_2O \longrightarrow \underset{H}{\overset{H_3C}{HC}}-\underset{OH}{\overset{CH_3}{C}}-CH_3 + H_2SO_4$$

---

[1] J. F. Norris and H. S. Davis, *J.S.C.I.*, 1929, **48**, 70T; *Brit. Chem. Abs.* **B**, 1929, 463; *Chem. Abs.*, 1929, **23**, 2932.

Class II. These are typified by the grouping:

$$\begin{array}{c}RC{=}CR' \\ H\quad H\end{array}$$

wherein R or R′ may be a hydrogen atom or an alkyl group. Such hydrocarbons are less reactive, both to sulphation and to polymerization, than are the corresponding tertiary compounds. Sulphation of these olefins requires acid of 75 to 85 per cent concentration, and little polymerization occurs. The products consist of sulphuric acid esters of secondary alcohols. This class is represented by *n*-alkenes, such as *n*-butene and *n*-pentene.

Class III. This very limited class is, at present, known to be represented by only one compound, isopropyl-ethylene. The hydrocarbon yields practically no sulphuric acid esters of the corresponding alcohol, but only polymerization products, when treated with acid of concentration higher than that required to react with the tertiary compounds of Class I.

Reactions of the Butenes. Of the four isomeric butenes (butene-2 existing as cis- and trans-isomers), isobutene is a typical tertiary olefin of Class I. This hydrocarbon dissolves smoothly in sulphuric acid of about 65 per cent concentration, and the resulting solution, on hydrolysis and neutralization, yields *ter*-butyl alcohol exclusively. If the acid solution is heated without dilution, polymers of isobutene (such as diisobutylene) can be recovered in good yield. The latter are useful as solvents, and in the production of high-octane motor fuels. Similarly, absorption of isobutene in sulphuric acid of concentration materially above 65 per cent yields polymer hydrocarbons at low temperatures.[2] According to Brooks,[3] isobutene can be selectively removed from a C_4 fraction, containing in addition *n*-butene and butadiene, by absorption in 65 per cent sulphuric acid at 10° to 15°C. without polymerization of the diolefin present. Mezhebovskaya[4] reported a study of a fraction, consisting largely of butenes, obtained by absorption of cracking gas on charcoal. This investigator observed that production of *ter*-butyl alcohol was maximal when the temperature of sulphation was −10° to +10°C., and the sulphuric acid concentration 75 to 65 per cent. Lower temperatures, and more efficient cooling, was needed when higher acid concentrations were used.

The sulphation and hydrolysis of butene-1 yields butanol-2, or *sec*-butyl alcohol, as does the similar treatment of either of the two isomeric forms of butene-2, i.e., *cis*-butene-2,  $\begin{array}{c}CH_3CH \\ \| \\ CH_3CH\end{array}$, and *trans*-butene-2, $\begin{array}{c}CH_3CH \\ \| \\ CHCH_3\end{array}$. In this conversion, however, acid of concentration ranging from 75 to 85 per cent is needed, although even stronger acid (90 to 100 per cent) has been suggested, when efficient refrigeration is employed.[5] With high acid concentrations, however, temperature regulation becomes progressively more difficult, while polymerization and side reactions increase in prominence. The normal butenes are rapidly sulphated in the liquid phase by 70 to 75 per cent sulphuric acid at 20° to 30°C., with little or no polymerization. Somewhat higher acid concentrations are advantageous, however, when treating liquid butenes diluted with relatively large proportions of saturated hydrocarbons, such as butane or isobutane. Under the conditions employed in the sulphation of normal butenes any butadiene present undergoes complete polymerization to high-boiling, unsaturated oils. These appear to result from the copolymerization of equimolar proportions of butadiene and *n*-butene.[6]

Pure normal butenes, on sulphation and hydrolysis, yield about 80 per cent of the theoretical quantity of butanol-2. Brooks[7] states that when the acid liquors are diluted with ice water, some 20 to 24 per cent of the alcohol obtainable is liberated as such. The remainder is secured only after heating the diluted liquor

Certain acid-soluble salts act catalytically to accelerate absorption of the olefins in sulphuric acid.[8] Silver sulphate, for instance, has a very pronounced effect on the absorption of ethylene, though the effect is progressively less with the heavier olefins. Vanadium, uranium and tungsten were much less effective. Markovich, Moor and Dement'eva[9] studied the use of a number of substances, including metallic salts and certain organic compounds. They point out that there are two phases of the problem to be considered; physical solution of the unchanged, unreacted hydrocarbon in the sulphuric acid during which the acid acts solely in the role of a solvent, and the subsequent chemical reaction of the acid and olefin. A few compounds insoluble in sulphuric acid were found to accelerate solution, without effecting chemical reaction. Although over thirty different compounds were investigated, ranging from the light alkali metals to the heavy metals such as uranium, it was found that silver salts (reacting to form silver sulphate) were most active. Some of the salts investigated retarded rather than accelerated absorption of the olefins.

The Pentenes. Trimethylethylene and unsymmetrical methylethylethylene are the five-carbon representatives of the Class I olefins noted above. These hydrocarbons can be converted almost quantitatively into *ter*-amyl alcohol by sulphation with 60 to 70 per cent sulphuric acid and subsequent hydrolysis. More concentrated acid results in considerable polymerization of the olefin.

Pentene-1 and pentene-2 are typical representatives of Class II olefins, giving practically theoretical yields of the secondary alcohols when treated with 82 to 90 per cent sulphuric acid (at 15° to 20°C.), followed by hydrolysis. Brooks,[10] however, has shown that pentene-1 yields only the acid esters of pentanol-2, that is, no *n*-amyl esters, when treated with 84 per cent sulphuric acid, even in the presence of a catalyst (hydrogen peroxide and benzoyl peroxide).[11] Under similar conditions, pentene-2 and 80 per cent sulphuric acid at 20°C. furnished a mixture of the esters of both pentanol-2 and pentanol-3, in ratio of 65 per cent of the former to 35 per cent of the latter. Thus, although the sulphate group attaches at either end of the double bond of pentene-2, it is directed to the more central carbon atom in pentene-1.

The pentene isopropylethylene is unique in that it forms mainly polymers when treated with 80 to 90 per cent sulphuric acid at 15 to 20°C. Practically no sulphated products result from this treatment, and lower concentrations of acid react only very slowly with the hydrocarbon. Brooks[12] suggests that the unique behavior is due to the formation of a tertiary alkyl sulphate rather than the secondary compound which might be expected. But since a high concentration of acid (80 to 96 per cent) is required to bring about reaction, the product when formed reacts as do other tertiary alkyl sulphates in acid of such concentration, and polymerizes rapidly. Brooks states that relatively large quantities of unsaturated oils arise from polymerization during the sulphuric acid treatment of pentene fractions from cracked petroleum. He believes the change is a manifestation of the tendency of certain olefins to copolymerize with other olefins which latter would not by themselves polymerize under the conditions that obtain.

[11] It has been found that peroxides exert a directive action in the combination of the halide acids with olefins, leading to the formation of primary alkyl halides. This is discussed in Chapter 12.

Pipik and Mezhebovskaya[13] conducted an investigation of the preparation of amyl alcohols from the pentene fractions of various cracked gasolines. As sulphating agents they employed sulphuric acid ranging in concentration from 75 to 85 per cent. Secondary amyl alcohols constituted the main products. The highest alcohol yields were found to result from treatment of 1 part of the amylene fraction with 1 to 1.3 parts of 75 per cent acid, or 0.75 part of 80 per cent acid. The light ends of a liquid-phase cracked gasoline furnished about 5.5 per cent by weight of amyl alcohols. A similar distillate obtained by vapor-phase cracking at 680°C. gave about 6 per cent of the alcohols. Pipik[14] subsequently observed that the hydrocarbons (boiling at about 55°C.) separated in the rectification of the amyl alcohols contained amylenes which, after treatment with additional acid, furnished more secondary amyl alcohols. It was noted that this amylene fraction contained an activator and was thereby rendered chemically active. The activated condition was considered to be further indicated by reaction with sulphur dioxide, which resembled that exhibited by the hydrocarbons of the isoprene series. The activator, however, could not be isolated.

Nazarov[15] reported a two-stage sulphation for preparing the pentyl alcohols from hydrocarbon fractions boiling below 30°C., between 30° and 40°C. and between 40° and 45°C. The material was subjected to a primary sulphation with 75 per cent sulphuric acid at 0° to —10°C. The product of this treatment was principally the tertiary alcohol 2-methylbutanol-2. The second treatment with 80 per cent acid at 20°C. yielded largely secondary pentyl alcohol, pentanol-2. These alcohols represented 39.3 per cent of the hydrocarbon undergoing reaction.

The Hexenes. The available data on the sulphation of the various hexenes is less complete than that concerning the lower members of the series. However, the tertiary olefins, tetramethylethylene and 2-methylpentene-1, are known to furnish the corresponding tertiary alcohols, 1,1,2-trimethylpropanol-1 and 2,2-dimethylbutanol-1, respectively, when sulphated with 75 to 80 per cent acid and subsequently hydrolyzed. Hexene-1 readily reacts with 85 per cent acid to yield (after hydrolysis) hexanol-2. Similarly, hexene-2 gives a mixture of 75 per cent of hexanol-2 and 23 per cent hexanol-3. The behavior of other hexenes towards sulphuric acid is still unknown. A gasoline fraction (boiling from 55° to 75°C.) was redistilled by Nazarov and Remiz[16] to obtain the fraction corresponding to the hexenes. It was found that there was a high benzene content in the 75° to 80°C. cut, and the investigators recommended that the lower boiling portion (from 55° to 75°C.) be used. On treating the latter first with 75 per cent sulphuric acid at 0°C. and then with 85 per cent acid at 5° to 10°C., followed by hydrolysis of the acid liquor, one tertiary alcohol, 2-methylpentanol-2, was recovered in 4.5 per cent yield, and the secondary alcohol hexanol-3 in 14.4 per cent yield (based on the total unsaturated hydrocarbons in the original fraction).

SEVERAL PROCESSES FOR THE SULPHATION OF OLEFINS

Tertiary Olefins. It is not practicable to separate by distillation[17] tertiary and secondary unsaturates occurring in the mixtures available for technical processes. However, advantage may be taken of the considerable differential in their reactivity with respect to sulphuric acid of various concentrations and a fairly complete separation may be secured in this way. The higher reactivity of the tertiary olefins makes possible a preferential conversion of these hydrocarbons to the sulphuric esters of the corresponding alcohols, while the less reactive secondary olefins remain substantially unaffected.[18] The residual olefins may then be treated with a more concentrated acid for the production of secondary alcohols. In carrying out this two-stage process, diolefins (such as butadiene) must be removed before the second step, otherwise co-polymerization of these with secondary olefins occurs. Perkins and Davies[19] prefer to separate the diolefins prior to the first sulphation treatment. A cracked hydrocarbon fraction consisting of four- and five-carbon atom chains, from which the diolefins had first been recovered, was treated with 55 to 65 per cent sulphuric acid at 10° to 35°C. to form a tertiary sulphate liquor, from which the corresponding alcohols could be recovered by hydrolysis. The hydrocarbon residue from this step was subsequently treated with 75 per cent sulphuric acid at a temperature below 20°C. to form a secondary sulphate liquor.

LeBaron[20] has described a procedure for sulphation of the butene fraction (in the liquid phase) separated from cracking gas. Sulphuric acid of 50 to 60 per cent strength is employed. The aqueous acid, containing tertiary butyl acid sulphate, is then removed and the residual liquid olefins treated with a second quantity of sulphuric acid of 65 to 70 per cent concentration. Brooks[21] proposes

[17] Although the most important technical source of olefinic material for the synthesis of alcohols is, perhaps, the unsaturated gases derived from cracking operations, other raw materials have been suggested. It has been reported, (S. V. Lebedev, V. P. Krause, I. A. Volzhinskii, Y. O. Gorin and O. M. Neimark, *Trudui Gosudarst. Opuit. Zavoda Sintct. Kauchuka Litera B. III., Synthetic Rubber,* **1934**, 68; *Chem. Abs.*, 1936, **30**, 4811.) that pseudobutene (butene-2) is obtained as a by-product in the preparation of synthetic rubber from bivinyl, and can be recovered by ordinary or vacuum distillation from the polymerizate. The investigators recovered secondary butyl alcohol in 83 per cent yield by treating the butene in the liquid phase with 75 per cent sulphuric acid. The unpurified gases from the polymerized product contain some bivinyl (up to 3 per cent) which could not be removed by treatment with sulphuric acid. An additional polymerization with metallic sodium did remove it, however. S. E. Campbell (U. S. P. 1.938.094, Dec. 5, 1933; *Brit. Chem. Abs.* **B**, 1934, 918; *Chem. Abs.*, 1934, **28**, 1180) has pointed out that hydrocarbon distillates may be decolorized by treating the material in towers successively with dilute sulphuric acid, alkali solution, concentrated acid, and a final water wash. Alcohols may be recovered by hydrolysis of the concentrated sulphuric acid liquors after dilution. The residual dilute acid from this latter step serves as the dilute acid of the first scrubbing tower.

to treat liquid butenes under superatmospheric pressure with about 63 per cent acid, to form an acid mixture containing monobutyl hydrogen sulphate. Water is then added and unreacted *n*-butenes separated from the resulting mixture Clark and Worster[22] suggested a countercurrent method of treating amylene fractions, with sulphuric acid of about 61 per cent concentration, to selectively react the tertiary hydrocarbons. The acid thus prepared is hydrolyzed afterwards by stirring with water and cooling below 30°C.

The removal of tertiary olefins and other highly reactive unsaturated hydrocarbons from their admixtures with secondary olefins may be effected by other means than sulphation. Polymerization may be carried out under such conditions as to convert these more reactive substances, without appreciable change of the secondary olefinic compounds. According to Engs and Moravec[23] the raw material containing both secondary and tertiary olefins may be treated with an acid of such strength as to bring about a substantially complete polymerization of the more reactive tertiary compounds, yet not strong enough (at the temperature employed) to materially polymerize the secondary compounds. The investigators point out, however, that this method may lead to an incomplete sulphation of the secondary olefins, thus reducing the yield of corresponding alcohols. They propose, therefore, to carry out the reaction in two separate steps. A butane-butene hydrocarbon fraction, for instance, may be first contacted (countercurrently) with 60 to 70 per cent sulphuric acid at 50°C. Under these conditions, isobutene is polymerized, while the butene-1 and butene-2 present are hardly affected. From this reactor, the fluid, now containing isobutene polymers, *n*-butenes, butane and isobutane is passed into a second reactor where it is treated with 90 to 100 per cent sulphuric acid, at a temperature of 15°C. In this latter operation sulphation of straight-chain butenes is effected. Above this temperature, it is reported, undesirable side reactions occur.

Hydrolysis and distillation of the resulting aqueous layer yield the secondary alcohol. If the polymers of isobutene have been attacked by the concentrated sulphuric acid in the second reactor, they revert to the original polymer under subsequent treatment and are readily separated. As an alternative procedure it is suggested[24] that tertiary olefins be selectively absorbed in sulphuric or phosphoric acid, which is removed and heated to approximately 80°C., causing polymerization of the dissolved hydrocarbon. The polymers may be separated from the acid, which is returned to the system for reuse. Sulphuric acid of 65 per cent concentration at a temperature of 55°C. may be employed in the absorbing chamber of this process.[25]

It has also been reported[26] that the presence of a bivalent metal sulphate in the sulphuric acid used in absorbing the olefinic material makes it possible to recover the tertiary olefins. These hydrocarbons dissolve readily in such a solution but may be released and recovered in a substantially pure condition on heating the liquid. Presumably polymerization is minimized by use of the soluble metal sulphate catalyst.

For the production of *ter*-butyl alcohol, Huyser and Van Melsen[27] propose to absorb the corresponding olefin in acid of concentration sufficiently low to prevent formation of any appreciable amount of polymerization products. They suggest the use of one hydrogen equivalent of acid (e.g., 65 per cent sulphuric acid) per mole of isobutene. It has been reported that the polymerization of olefins in the presence of sulphuric acid is inhibited by the addition of cyanides or complex cyanides of platinum, copper, iron, cobalt, nickel or silver.[28] The salts of metals of the 8th group of the periodic table, e.g., nickelous cyanide, $Ni(CN)_2$, are said to facilitate absorption of the olefinic material in the acid.[29] Cuprous salts have also been suggested for the same purpose.

In sulphating a mixture of olefins and diolefins derived from cracking processes, Brooks[30] suggests a fraction containing mainly butenes and butadiene. Diolefins are first removed (without polymerization) by contact with a slurry of cuprous chloride in an aqueous ammonium chloride solution. The remaining mixture is then freed of tertiary olefins with 60-65 per cent sulphuric acid at 25°C. or lower. Subsequent treatment with 65-75 per cent acid at 35-60°C. removes the normal butenes, and the propene remaining is then absorbed by 80-85 per cent acid at 20-40°C. If any ethylene remains in the unabsorbed portion, this may be sulphated with 85-95 per cent acid at 30-100°C.

According to some investigators,[31] solution of an olefin in aqueous sulphuric acid can be effected to produce a liquor containing most of the absorbed olefin in the form of the free alcohol, which can be separated by solvent extraction. For example, isobutene may be absorbed in 58 per cent sulphuric acid (containing 0.5 per cent of cuprous oxide) at 50°C. under atmospheric pressure. The resulting liquor (possessing 250 grams of free *ter*-butyl alcohol per liter) is extracted with one and a half times its volume of cresol. On extraction, the solvent is said to contain 100 grams of alcohol per liter, while the acid liquor contains an equal concentration of the alcohol. After washing with water to remove entrained acid, alcohol and solvent are separated by fractionation and the latter reused. This process is said to be advantageous in that it obviates the necessity of diluting and reconcentrating the sulphuric acid. The same type of treatment is reported efficacious with trimethylethylene, using 50 per cent sulphuric acid in this case, and ethylphenol as the extracting solvent. The extract finally contains upwards of 20 per cent of *ter*-amyl alcohol.

Secondary Olefins. In converting butenes and pentenes into sulphuric acid esters of the corresponding alcohols, the usual practice is to contact the olefin (often in the liquid phase) under slight pressure with sulphuric acid of the requisite concentration. Careful control of temperature is also necessary. Tertiary olefins and diolefins are removed prior to the sulphation, since undesirable side reactions and polymerizations tend to occur if they are present. Depending on temperature, acid concentration, and the relative proportions of olefin material to acid employed, secondary olefins may be converted to mono- or di-sulphates, or into polymerization products. At normal temperatures, acid concentrations of approximately 80 per cent appear to be best for the production of alcohols, but stronger acid may be used under low-temperature conditions. Employment of

stronger acid, however, makes the accurate control of temperature more difficult and at the same time more important if polymerization is to be minimized. Perkins and Davies[32] produced secondary alkyl sulphate liquors by treating a mixture of four- and five-carbon atom olefins, previously freed of diolefins and tertiary olefins, with 75 per cent sulphuric acid at temperatures below 20°C. The *n*-butenes (in the butane fraction of cracking gas) may be sulphated in the liquid phase with sulphuric acid of 65 to 70 per cent strength according to LeBaron.[33] Iso-olefins are first removed by treating the fraction with 50 to 60 per cent acid. Brooks[34] suggests that sulphation reactions may be controlled effectively by adding the liquid olefin to the sulphuric acid in such manner that the ratio of acid to olefin is maintained in excess of that required to form the monoalkyl sulphate.

Dialkyl sulphates may be prepared by treating *n*-olefins of four or more carbon atoms with 90 to 100 per cent acid, after the iso-olefins have been removed with 65 to 70 per cent sulphuric acid. For example, dibutyl sulphate may be obtained by the action of sulphuric acid (one mole) on liquid butene (two moles).[35] Concentrated acid of 90 to 100 per cent strength has also been used by Engs and Moravec[36] at temperatures below 47°C., but in this case, approximately equivalent proportions of the reactants were employed. The secondary alcohols are obtained by dilution of the alkyl sulphate solution to 25 or 35 per cent acidity.

It has been reported that metal cyanides present in 90 per cent acid not only act to inhibit polymerization of absorbed olefins but also do not promote esterification. The complex resulting from the interaction of unsaturated hydrocarbons, cyanides and acid is said to have a pronounced catalytic effect in facilitating the solution of further olefinic material. The strong acid solution containing the complex, after dilution, may be used in absorbing further quantities of hydrocarbons.[37] A catalyst composed of a compound of a metal of group VIII, such as ferrocyanic acid, has been proposed for absorption of cyclic unsaturated hydrocarbons, such as cyclohexene, in 80 per cent sulphuric acid. Subsequent hydrolysis furnishes the cyclic alcohol.[38]

Davis and Francis[39] report that heating (at 84 to 95°C. under 500 pounds per square inch pressure) a readily sulphated olefin, such as propene or butene, with an aqueous solution of the sulphuric acid ester of an olefin more difficult to sulphate (e.g., ethyl sulphate) results in a mixture of ethyl alcohol and the alcohol corresponding to the olefin introduced into the solution.

One of the main difficulties associated with the reaction between the higher olefins and sulphuric acid, of concentration greater than 90 per cent, is that considerable heat is evolved. This means that temperature regulation becomes important, if polymerization is to be controlled, since a rise in temperature brings about the formation of increasing proportions of polymers. For this reason, reaction is usually carried out in the liquid phase (and under pressure, if necessary) in vessels equipped with agitating devices and internal cooling coils. However, Deanesly[40] takes advantage of the volatility of the hydrocarbons being sulphated to regulate the temperature. He proposes that an olefin-containing mixture and sulphuric acid be intimately contacted in a packed column. The heat of reaction vaporizes a portion of the hydrocarbon, and these gases are collected, condensed, and reintroduced at a higher point in the column. Sufficient hydrocarbon is present, however, to insure that there shall be liquid material in the reaction zone at all times. Accurate temperature control is possible in this way, it is said. Alternatively, Young[41] produces alkyl sulphates by forcing a liquefied olefin and 75 to 100 per cent sulphuric acid at temperatures below 40°C. countercurrently through a flow path of restricted cross section. The length of the path is such that reaction will be substantially complete within it. The suggested form of the apparatus consists of a bank of relatively small-bore tubes immersed in a cooling medium. Kramer,[42] on the other hand, reported a method of control of the temperature of reaction by allowing interaction to take place in a comparatively large mass of fluid. The latter is recirculated, and cooled below the desired maximum temperature, so that the heat generated during interaction shall not be great enough to unduly increase the liquid's temperature. The fluid may consist of an inert liquid, one of the reacting substances present in great excess, or a by-product of the reaction. In the latter case, the substance employed is so chosen that it may be readily separated.

LeBaron[43] described a method which involved a series of steps, each individually controlled as to acid concentration and temperature. The raw hydrocarbon material is mixed with sulphuric acid of relatively low concentration and the acid reaction product separated from the unreacted hydrocarbon. The unchanged olefinic material then passes to a second zone, where more concentrated sulphuric acid is contacted with it. The hydrocarbon and acid in each zone are reacted while flowing in a continuously moving stream, the temperature of which is controlled to prevent undesired side-reactions, while permitting sulphation of the olefin. A number of these successive reactions may be used, the hydrocarbon meeting successively stronger acid in each.

Markovich and Pigulevskii[44] sulphate the normally gaseous products of pyrolysis by adding sulphuric acid in batches to the hydrocarbon material, which is maintained in the liquid state by the application of pressure, or by solution in higher hydrocarbon fractions. The process temperature is allowed to rise during the reaction from 0°C. to a final value of about 60°C.

The reaction between liquid olefins and sulphonic acids, such as benzenesulphonic acid, may be employed as an intermediate step in the formation of the alkyl esters of organic acids.[45] The sulphonic acid and the olefin are reacted with agitation at a temperature from 25° to 100°C., and the resulting alkyl sulphonate ester is heated with an appropriate organic acid (e.g., acetic acid). Alternatively, the olefin and the organic acid may be directly heated together in the presence of the benzene sulphonic acid, the two reactions proceeding simultaneously.

HYDROLYSIS OF ACID LIQUORS AND RECOVERY OF ALCOHOLS

The usual method for recovery of the alcohols from the acid liquors obtained by absorption of olefins in sulphuric acid consists, broadly, in dilution of the liquors with water, followed by distillation.[46] The residual dilute acid is then reconcentrated for further use. However, it being known that the tertiary alcohols are rather easily dehydrated to olefins under the influence of quite dilute (0.02 normal) mineral acids, in consequence, practice has sometimes been to neutralize the acid prior to distillation for recovery of such alcohols. Thus, Moravec and Engs[47] add sufficient basic material (e.g., ammonia) to the acid liquor to bring about separation into two layers. The alcohol phase is withdrawn and distilled. Brooks[48] states, however, that the dehydration may be prevented if the distillation is carried out in a vitreous tower countercurrent to steam. Metal, he finds, tends to catalyze the reaction resulting in decomposition of the alcohol. The operation should be rapid and continuous, and under these conditions, it has been found possible to recover 80 per cent of the *ter*-butyl alcohol present in acid solutions containing as much as 35 or 40 per cent sulphuric acid. Prior to distillation, the diluted acid liquor is hydrolyzed by heating at temperatures from 50°C. up to the boiling point of the alcohol. Shtakelburg[49] also reported that the hydrolysis of *ter*-butyl and *ter*-amyl sulphuric acid esters could be accomplished by distillation countercurrent to steam. Higher alcohol concentrations were obtained by this method than by alkaline hydrolysis.

In the commercial manufacture of the secondary butyl and amyl alcohols, sulphation is generally carried no further than the formation of the monoalkyl sulphate, since this minimizes the development of ethers (which are largely due to dialkyl sulphates). When the dialkyl sulphates are formed, they are precipitated from the acid liquors on dilution with water, and can be withdrawn and hydrolyzed separately. The latter step, in the case of higher monoalkyl sulphates, is catalyzed by sulphuric acid, but requires an appreciable time to proceed to completion even at temperatures up to the boiling point of the alcohol. The hydrolysis time of secondary amyl sulphate under various conditions of temperatures and acid concentration has been studied by Brooks.[50] The results graphically depicted in Fig. 106 represent the effects of varied acid concentration at constant temperature, and strongly indicate the catalytic effect of the hydrogen ion. It will be noticed that in a weakly basic solution, even after three hours, less than 35 per cent hydrolysis had taken place, while in a solution originally 5.6 normal, 93 per cent hydrolysis had occurred in one-half hour. The influence of temperature is shown in Fig. 107. The curves suggest the advisability of using temperatures and acid concentrations as high as possible, while avoiding excessive polymerization. In the case of butyl, amyl and hexyl alcohols, the decomposition of the sulphates to olefins is an important factor in lowering the overall efficiency of the sulphation process. Engs and Moravec[51] suggest that acid liquors, obtained by the solution of secondary olefins in about one equivalent of 90 to 100 per cent sulphuric acid, be diluted to 25 or 35 per cent acid content, and heated.

FIG. 107.—Influence of Temperature on the Hydrolysis of *sec*-Monoamyl Sulphate. (B. T. Brooks)

If the mixed secondary and tertiary olefins are absorbed in 90 to 100 per cent sulphuric acid, and allowed to stand, separation takes place. The polymerized tertiary olefins form an oily upper layer, while the secondary alkenes and sulphuric acid compose the lower layer. This latter acid layer is separated, and diluted with water sufficient to give about 15 per cent concentration of acid. The dilute solution is heated to effect hydrolysis, and distilled to recover the alcohols.[52] Engs and Moravec[53] also described a method of producing secondary alcohols in which the diluted liquors are hydrolyzed by heating to a temperature below that at which the alcohol produced distills off. The acid released by this hydrolysis is neutralized before the alcohol is recovered by distillation. In this manner acidity is reduced to a value below that maintained during hydrolysis. Thus, the hydrolytic operation may be carried out at 40° to 100°C. (e.g., 50°C.) in 30 to 40 per cent sulphuric acid solution, and ammonia added to counteract the acid set free.

In converting dialkyl sulphates into the corresponding alcohols, these investigators[54] treat the compounds with aqueous sulphuric acid (of 60 to 85 per cent strength) to produce first the corresponding monoalkyl sulphates. The latter, in turn, are converted into alcohols by further treatment with water.

When the acid liquors obtained by absorption of secondary olefins in sulphuric acid are diluted, separation ensues, forming two layers. The upper consists largely of hydrocarbons, with some alcohols in solution, while the lower contains the aqueous sulphuric acid solution of the esters. Brooks reports that the secondary alcohols contained in the hydrocarbon layer may be recovered either by washing with aqueous sulphuric acid of 2 to 10 per cent concentration,[55] or by distillation.[56] Simultaneous hydrolysis and separation of the secondary alcohols may be effected, according to Shiffler and Holm,[57] by introducing the diluted olefin-sulphuric acid liquor into the middle section of a reflux still. Alcohol-free sulphuric acid of 70 per cent strength is continuously withdrawn from the foot of the still, while alcohol-rich distillate is obtained at the top. Steam is continuously returned to the lower end of the column to insure complete vaporization of the alcohol.

In the production of butyl, amyl, hexyl and heptyl alcohols, Archibald and Janssen[58] propose to dilute acid reaction liquors with water to an acid concentration between 15 and 50 per cent. The resulting liquid is allowed to stratify, the temperature being kept between 20° and 60°C. as determined by the acid concentration; the higher temperature when settling the more dilute liquors. Under proper conditions, the liquid forms three layers, the top one consisting mainly of polymerized oils, the middle phase containing the major portion of the alcohols, and the bottom layer being dilute acid with only a small proportion of alcohols. The two lower phases may be separately worked up for recovery of the alcohols, e.g., by distillation. Davies[59] proposes, on the other hand, that after separation resulting from the water dilution of the acid liquors, an organic liquid miscible with both layers, such as methanol, ethanol or acetone, be added. The homogeneous mixture which results is hydrolyzed, and the desired alcohols recovered by fractional distillation. Merley[60] treats the alkyl sulphates with such a compound as hexyl acetate, instead of directly hydrolyzing the sulphates to alcohols. The sulphate

and the acetate are mixed by vigorous agitation, without heating, and an anhydrous salt of a monocarboxylic acid (e.g., calcium acetate) is added slowly. The mixture is then heated to complete the reaction, and dry aliphatic alcohol is added to neutralize any excess organic acid evolved. The mixture is refluxed and dry lime is added to neutralize any free sulphuric acid. The resulting alcohols and esters are dry distilled.

Polymerized hydrocarbons may be removed from the hydrolyzed sulphate liquors by repeated extraction with a water-immiscible solvent which is capable of forming azeotropic mixtures with water, (e.g., benzene, carbon tetrachloride, ethylene dichloride, cyclohexane, or propyl acetate). The extract and the raffinate are separated, and the latter is distilled to give an aqueous alcohol distillate. This is then subjected to azeotropic distillation in the presence of the extraction agent to obtain finally water-free and polymer-free alcohol.[61] Carney,[62] on the other hand, reports that dehydration may be effected by rectification of aqueous alcohol in the presence of an agent which does not form azeotropic mixtures. Dehydration is brought about by adding a paraffin hydrocarbon in the vapor phase at atmospheric pressure, and distilling off water vapor and the paraffinic compound under reduced pressure. The added compound is substantially insoluble in water, but miscible with the anhydrous alcohol. Removal of impurities of disagreeable odors (such as polymerized hydrocarbons) from diluted or neutralized sulphuric esters may also be achieved by extraction with the sulphur dioxide (Edeleneau) extract of mineral oil, or similar material of appropriate boiling range.[63] It has also been proposed that the separation of the polymers may be effected by a three step process. In the first stage, the diluted acid liquor is distilled to obtain an azeotropic ternary mixture of alcohol-water-polymer composition. This distillate is dehydrated by employment of solid drying agents such as copper sulphate, calcium oxide or calcium chloride. The dried alcohol-polymer mixture can then be fractionated to yield alcohol substantially free of polymers.[64]

Tertiary alcohols admixed in secondary olefins may be removed by prolonged refluxing with sulphuric acid, or similar mineral acid of low volatility.[65] Concentrated sulphuric acid diluted with not more than its own volume of water is added (in quantity of about 10 to 20 per cent by volume) to the material to be treated. The tertiary alcohols present are dehydrated to olefins, and readily separated. Objectionable sulphur compounds, such as mercaptans, which impart odor or color to the alcohols may be removed from isopropyl and higher secondary alcohols by washing with an aqueous solution of sodium plumbite.[66] Aliphatic alcohols of from 3 to 7 carbon atoms may be freed of organic sulphur and oxygenated compounds imparting objectionable odors by subjection to the action of brass turnings at 350-600°C. Iron sulphide or cobalt oxide may also be employed. The vapors are contacted with the catalyst at the rate of 2 to 5 volumes of alcohol (liquid) to 1 of contact agent per hour.[67] Archibald and Janssen[68] advise refining the olefinic materials from which alkyl sulphates and, subsequently, alcohols are to be made before acid treatment. They suggest passing the hydrocarbon in vapor phase over a refractory catalyst such as bauxite, kaolin or silica gel at a temperature of 225° to 500°C. The treated material is then scrubbed with sodium hydroxide to remove hydrogen sulphide, and subsequently contacted with acid to remove tertiary olefins. The secondary olefins remaining can then be converted to alcohols.

Chapter 17

Properties and Uses of Higher Secondary and Tertiary Alcohols Derived from Olefins

The two types of alcohols produced from olefins of more than 3 carbon atoms are sharply differentiated in both chemical and physical properties. In the discussions of the preceding chapters reference has been made to the readiness with which tertiary alcohols are dehydrated to olefins, the ease with which the latter polymerize, and to the greater stability of the corresponding secondary alcohols. It is evident that this sharp distinction will materially influence the utilization and economic value of the two classes of compounds. It is not surprising then, that heretofore the secondary alcohols have found more extensive commercial application, particularly in the form of their esters, than the tertiary alcohols.

So far as is known, no primary alcohols are formed in the hydration of olefins by the sulphuric acid method, although the remarkable influence of the peroxides on the combination of olefins with the hydrogen halides would indicate the possibility of obtaining primary alcohols by the intermediate formation of the corresponding alkyl chloride or bromide.[1] Since the higher primary alcohols possess certain definite advantages over the corresponding secondary and tertiary alcohols, any commercially feasible method of producing them directly from olefins would be highly attractive. So far, however, no such method has been introduced.

PROPERTIES OF SECONDARY ALCOHOLS

Perhaps the most characteristic reactions of the secondary alcohols are those of dehydration and dehydrogenation. The last-named reaction may be effected either catalytically at temperatures above 200°C. or by oxidation in the vapor phase with a limited amount of oxygen or air, to yield the corresponding ketones. Primary alcohols under like treatment furnish aldehydes, whereas tertiary alcohols do not undergo this simple type of dehydrogenation. The production of ketones from secondary alcohols either by oxidation or catalytic treatment is important industrially and is discussed in Chapter 18. Oxidation of secondary alcohols in chromic acid-aqueous sulphuric acid solution may be rendered quantitative, and serves as a general method of estimating the individual alcohols of this class. By isolation and identification of the ketone produced under these circumstances, the related alcohol can be simultaneously identified and determined.

Dehydration of Secondary Alcohols. Dehydration of these alcohols to the corresponding olefins proceeds, in general, more readily than that of primary and much less easily than with tertiary alcohols. It may be accomplished either in the vapor phase employing contact agents such as alumina, thoria, zirconia or certain acid phosphates of cadmium or manganese, or in the liquid phase in the presence of such strong mineral acids as phosphoric or sulphuric. The exact composition of the olefin mixture formed depends to a large extent on the nature of the catalyst and the operating conditions. Considerable polymerization is frequently encountered, inasmuch as these dehydrating catalysts are usually polymerizing agents as well.[2] Thus, dehydration of the pentanol, 1,2-dimethylpropanol-1, in the presence of 75 per cent sulphuric acid at 80°C., yielded two decenes, 3,5,5-trimethylheptene-2 and 3,4,5,5-tetramethylhexene-2, in about equal quantities.[3]

---

[1] See Chapter 33.

On the other hand, Drake and Veitch[4] point out that butanol-2 treated in a similar manner (with 75 per cent sulphuric acid at 80°C.) furnishes no appreciable quantity of octenes. Despite the fact that reaction temperatures were varied from 25° to 100°C. and acid strengths from 50 to 90 per cent, no perceptible yield of the dimer of butene could be obtained. In this case, butene was formed so rapidly, it was believed, that the olefin escaped from the reaction zone before polymerization took place. However, when acid concentration greater than 90 per cent was used, a high-boiling polymer of the type $(C_4H_8)_x$; where x was greater than 2, was secured.

Experiments were undertaken in which the escape of the butene was prevented, and polymerization took place under pressure at 80°C. in about 48 hours, when using acid of 75 per cent strength. Still, however, the yield of octene was low, due to the readiness with which it, in turn, polymerized to still higher olefins. Distillation of this unsaturated hydrocarbon in the presence of a very small quantity of acid resulted in the formation of these higher polymers and also a considerable proportion of di-*sec*-butyl ether in the higher boiling fraction. Ozonolysis of the octene fraction indicated that it was largely 3,4-dimethylhexene-2.[5]

According to Komarewsky, Johnstone and Yoder,[6] there has been some disagreement as to the butenes produced by the dehydration of butyl alcohols. They suggest that a part of the difficulty may have been in the identification of the butenes when the determination was made by bromination of the product. It is proposed that careful fractionation of the butene itself be relied on.

This method of analysis showed that the products of dehydration of *sec*-butyl, alcohol, over a catalyst of phosphoric acid on alumina, were butene-1 and butene-2 in the ratio of 1 to 8. These investigators report that phosphoric acid has a distinct tendency to bring about isomerization of the unsaturated compounds produced, to an extent varying, apparently, with the type of catalyst support used. Thus, when the phosphoric acid on alumina was substituted by phosphoric acid on pumice, the dehydration products were butene-1 and butene-2, but in ratio now of 47.5 per cent to 52.5 per cent.

Dehydration of the higher secondary alcohols often takes an unusual course, with the result that no hypothesis of mechanism hitherto advanced adequately explains the observed results. The usual result of such reaction is a β-alkene, but in several instances considerable quantities of the α-alkene have been reported. Thus, Whitmore and Homeyer[7] report dehydrating the *sec*-heptanol 4,4-dimethylpentanol-2 by distillation from 100 per cent sulphuric acid. Two heptenes were obtained, 4,4-dimethylpentene-1 and 4,4-dimethylpentene-2, in the ratio of 18 to 82. Phosphoric acid, Whitmore and Herndon[8] found, converts octanol-2 (capryl alcohol) into a mixture of octene-1 and octene-2, but in this case the α-octene exceeded the β-octene by 2 to 1. Under pressure and at higher temperatures, extensive rearrangement of the products of a dehydration reaction may take place. Whitmore and Meunier[9] observed that *ter*-butylmethyl carbinol, (3,3-dimethylbutanol-2) at 300°C. and under 2500 pounds pressure furnished only a small yield of 3,3-dimethylbutene-1. The bulk of the product was a mixture of the rearranged olefins 2,3-dimethylbutene-2 and 2,3-dimethylbutene-1 in the ratio of 2 to 1.

More extensive rearrangement takes place in the case of di-*ter*-butylcarbinol (2,2,4,4-tetramethylpentanol-3) when employing 1-chloro-4-naphthalenesulphonic acid as a dehydrating catalyst. This, probably, is not unusual since neither of the carbon atoms (in this alcohol) next to the carbinol group possesses an attached hydrogen atom. Whitmore and Stahly[10] report that when the reactants were heated in a flask immersed in an oil bath at 180°C., there was no evolution of gas until practically the theoretical quantity of water had escaped. At this point, the distillation temperature dropped sharply from 88° to 34°C., trimethylethylene distilled over, and gas was evolved. After one and one-half hours, the distillation temperature rose, and higher olefins appeared. It was found that a 77 per cent yield of trimethylethylene had been obtained, together with smaller quantities of mixed nonenes, diamylenes and triisobutylenes, while the gas which had been evolved proved to be isobutene. However, when the dehydration was conducted below 155°C., and the water formed was allowed to reflux, splitting of the hydrocarbon molecule did not occur. In this instance nonenes to the extent of 71 per cent were formed. When the latter, admixed with the chloronaphthalenesulphonic acid, were heated to 145-205°C., then decomposition did occur. The hydrocarbon products thus obtained consisted of 68 per cent trimethylethylene, 50 per cent isobutene and 39 per cent polymers.

Condensation With Aromatics. Secondary alcohols condense with aromatic hydrocarbons in the presence of sulphuric acid, to yield the corresponding secondary alkyl derivative. Kirrmann and Graves[11] prepared isopropylbenzene and polyisopropylbenzenes by this type of reaction, using benzene and isopropyl alcohol in the presence of concentrated sulphuric acid. Toluene and isopropyl alcohol yield both the ortho and para derivatives of cymene, when the condensing agent is 80 per cent sulphuric acid.[12] According to Durand,[13] the original discovery of the interaction of alcohols with benzene hydrocarbons was made by Liebmann,[14] and subsequently extended by Goldschmidt,[15] Brochet and LeBoulenger,[16] and Verley.[17]

Tzukervanik[18] points out that combination of benzene with secondary or tertiary alcohols can be effected most readily in the presence of aluminum chloride. This investigator believes that reaction probably involves the intermediate formation of alcohol-aluminum chloride complexes of the type $AlCl_2(OR)$ (with elimination of hydrogen chloride) as these have been shown to result on treatment of primary

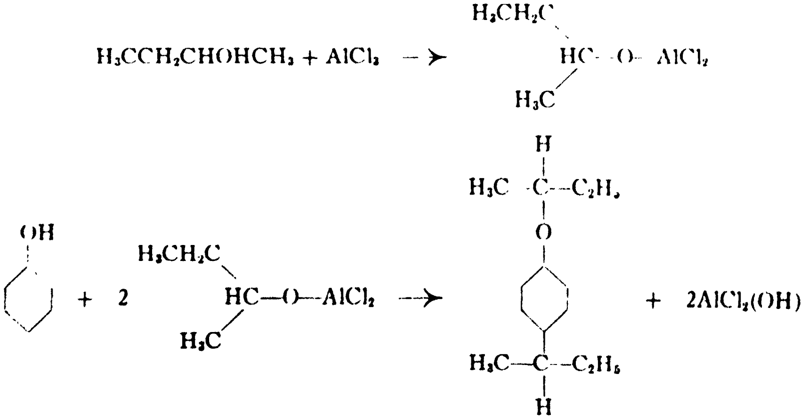
alcohols with the metallic halide. Tzukervanik and Tokareva[19] observed that isopropyl and *sec*-butyl alcohols reacted with benzene and toluene (in the presence of the Friedel-Crafts reagent) to yield up to 70 per cent of alkylated hydrocarbons. If an excess of aluminum chloride is used, some dialkyl derivatives are secured. With toluene, the alkyl group is directed to the para position. Thus, 30 g. of isopropyl alcohol; 150 cc. of benzene and 43 g. of aluminum chloride gave 35 g. of a liquid fraction consisting of cumene and diisopropylbenzene. The same quantities of isopropyl alcohol and aluminum chloride reacted with 100 cc. of toluene yielded 35 g. of *p*-cymene. Secondary butyl alcohol (20 grams), benzene (100 cc.) and aluminum chloride (30 grams) furnished *sec*-butylbenzene.

Condensation With Phenols. Huston and Hsieh[20] have investigated the reactions of secondary, tertiary and primary alcohols with phenol and benzene derivatives in the presence of aluminum chloride. They report that, as a general rule, tertiary alcohols condense readily with phenols to give good yields of *p-ter*-alkylphenols (45 to 60 per cent). Under the same conditions, isopropanol gave a small yield of a substance which was not identified, but did not correspond in properties to any known propyl phenol or phenyl propyl ether. Neither *sec*-butyl alcohol nor primary alcohols reacted with benzene. Tertiary alcohols did so readily, and gave good yields (65 to 70 per cent) of products. Secondary alcohols reacted more slowly, and resulted in lower yields of alkylbenzenes, and the primary alcohols did not condense under the conditions obtaining. Tzukervanik and Nazarova[21] observed that tertiary alcohols and phenol furnished yields of 60 to 70 per cent of alkylated phenols (together with alkylated benzene hydrocarbons as by-products). Furthermore, these investigators are of the opinion that the use of secondary alcohols gives rise mainly to ethers of alkylated phenols. Thus, they report obtaining isopropylcumyl ether ($C_3H_7—C_6H_4OC_3H_7$) from isopropanol and phenol. This difference in the reactions of secondary and tertiary alcohols (under the influence of aluminum chloride) is attributed to the fact that secondary alcohols do not readily yield considerable amounts of olefins and alkyl halides, whereas the tertiary alcohols do. Condensation of secondary alcohols is believed to take place according to the following scheme:



---

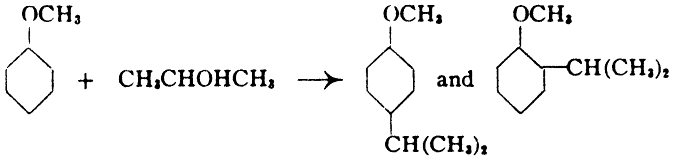
[21] I. Tzukervanik and Z. Nazarova, *J. Gen. Chem. (U.S.S.R.)*, 1935, 5, 767; *Chem. Abs.*, 1936, 30, 443.

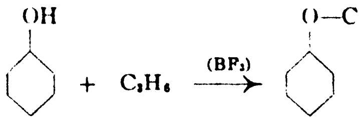
In confirmation of this proposed mechanism, it is pointed out that isopropyl alcohol and anisole (phenylmethyl ether) in the presence of aluminum chloride furnish a mixture of *o*-and *p*-isopropylanisole:



Smith[22] reports that considerable rearrangement of alkyl phenyl ethers may take place in the presence of aluminum chloride. Thus, *sec*-butylphenyl ether is transformed into *p*-*sec*-butylphenol. This investigator states the corresponding *ter*-butylphenyl ether rearranges so readily that it cannot be distilled at atmospheric pressure without thermal isomerization to *p*-*ter*-butylphenol taking place. Such change occurs even more rapidly with the condensation product of isobutyl alcohol and phenol, it is said, so that there is some doubt that isobutyl phenyl ether can be prepared, the substance actually obtained being the isomer, *ter*-butylphenol.

That boron trifluoride exerts catalytic action in bringing about the interaction of secondary alcohols and phenols has been demonstrated by Sowa, Hennion and Nieuwland.[23] They reacted 60 grams of isopropyl alcohol with 94 grams of phenol in the presence of 24 grams of the trifluoride. A mixture of alkylated phenols and phenol ethers was secured, 47.5 per cent of which was 2-isopropylphenol, 34 per cent 4-isopropylphenol and 18.5 per cent of 2,4-diisopropylphenylisopropyl ether. Since investigation showed that isopropylphenyl ether did undergo rearrangement,[24] as exhibited by butylphenyl ethers, it was believed that this alkylation of phenol in the presence of boron trifluoride involved a primary dehydration of the alcohol to the olefin and the subsequent condensation of the unsaturated hydrocarbon with phenol:

$$C_3H_7OH \longrightarrow C_3H_6 + H_2O$$



Langwell[25] reports that zinc chloride in 80 per cent aqueous solution will serve as the condensation catalyst in this reaction. When secondary alcohols are employed a temperature of about 130°C. is required, as for example, the interaction of phenol and *sec*-isohexanol. In the case of primary alcohols, a temperature of 180°C. is necessary. A volatile hydrocarbon such as isohexene or benzene may be added, and reaction carried out under reflux. Bertonasco[26] reports that warming resorcinol with *sec*-butanol and concentrated sulphuric acid produces a dye. The products are, it is suggested, esters of resorcinol-disulphonic acid.

Physical Properties. The boiling points and densities characteristic of the more important secondary alcohols of the lower range are given in Table 96.

Relatively few of these have been definitely identified among the complex mixture obtained by the sulphation of the higher olefins. The most important secondary alcohols being produced from the lower olefins aside from isopropanol are, perhaps, butanol-2, pentanol-2 and pentanol-3, and secondary hexyl and heptyl alcohols of undetermined structure.

The water solubilities of secondary alcohols above isopropyl alcohol decrease rapidly. Although the latter is miscible in all proportions with water, butanol-2 and pentanol-2 dissolve to a limited extent in water, and pentanol-3, hexanol-2 and hexanol-3 are very slightly soluble. The secondary heptanols and octanols are practically insoluble, as are the higher members of the series. Although butanol-2 is somewhat soluble in pure water, it may readily be salted out of solution by addition of calcium chloride. Thus, Shaposhnikov and Pinchuk[27] find that butyl and higher alcohols may be determined quantitatively by this method. They suggest adding 4 cc. of the solution to be tested to 20 cc. of aqueous calcium chloride (of density 1.16) which has been saturated previously with butyl alcohol. The higher alcohols are sufficiently insoluble so that the solution of the chloride need not be saturated with them, presumably. Separation occurs under this treatment, and the alcohol layer formed contains the butyl and higher alcohols present together with any hydrocarbons. The latter are determined by adding 35 volumes of water, to the alcohol layer, and noting volume of hydrocarbons formed. This quantity is subtracted from that previously ascertained as representing alcohols and other liquids.

TABLE 96.—*Some Higher Secondary Aliphatic Alcohols.*[28]

Alcohol	Boiling Point °C.	Melting Point °C.	Density 20°/4°C.	Molecular Weight
Butanol-2	99.5		0.808	74.08

ESTERS OF THE HIGHER SECONDARY ALCOHOLS

The esters of the secondary alcohols, particularly the acetates, are important as solvents in the lacquer and varnish industry. Parks and Hopkins[29] report that the secondary acetates are miscible in all proportions with the other solvents and diluents commonly used in the production of lacquers, and may be employed in any desired proportion. Asphalt, tars, pitches, rosin, ester gum and many other resins are soluble in these liquids, although shellac is not. The physical characteristics of mixtures of 85 per cent secondary acetates with about 15 per cent of the corresponding alcohols are summarized in Table 97.

[29] J. G. Parks and M. B. Hopkins, *Ind. Eng. Chem.*, 1930, 22, 826; *Chem. Abs.*, 1930, 24, 4646;

TABLE 97.—*Properties of Secondary Acetates (With 15 Per Cent of Alcohol)*

Ester	Boiling Point °C.	Density 15.5/18.5°C.	$N^{20°C.}$
sec-Butylacetate	107-114	0.861	1.3915
sec-Amylacetate...	128-134	0.863	1.4021
sec-Hexylacetate....	146-156	0.863	1.4081

The solvent power of these esters, as evidenced by dilution ratios and viscosity measurements of cellulose nitrate solutions, is only slightly less than that of the corresponding primary esters, it was reported. Parks and Hopkins also point out that the solubility of water in the solvent is an indication of the probable tendency of that medium to cause blushing in humid weather. As a general rule the aliphatic esters boiling above 100°C. are only very slightly miscible with water, and therefore have good blush resistance. Very little difference was observed in this respect between normal and secondary esters. Sayers, Schrenk and Patty[30] made a study of the physiological properties of commercial butyl acetate. The characteristic action of pure *n*-butyl acetate appears to be strongly narcotic, with the expected consequence of coma and death if the vapors are breathed in high concentration. Animals which were exposed to the fumes and narcoticised recovered completely if death did not take place during the period of exposure. Commercial butyl acetate produces symptoms of nasal and eye irritation, and narcosis. At room temperature, however, it was not possible to attain a concentration of vapor that was dangerous to the life of guinea pigs in 30 to 60 minutes. Exposure to 1 to 1.4 per cent vapor concentration is dangerous, however, after several hours. Concentrations greater than 0.7 per cent cannot be endured without effects more serious than the eye and nose irritation within one hour. If exposure is continued for several hours, 0.33 per cent is the maximum that can be tolerated with but slight, or no symptoms. The commercial material used in the investigation had a marked odor, and was found to be distinctly irritating (to the nose and eyes of men) in concentrations apparently harmless to guinea pigs after a single exposure of several hours' duration. The lower inflammability limit was estimated to be approximately 1.7 per cent, but concentrations well below this figure are extremely disagreeable to men from the standpoint of odor and eye and nose irritation, it was reported.

Bass and Fenn[31] describe the preparation of *sec*-butyl lactate (boiling at 172°C., density 0.972) by heating butanol-2 and anhydrous lactic acid at 170° to 175°C. for four hours in a pressure vessel. An acid catalyst may be used to promote esterification. The product is then separated by fractionation. Cyclohexanol may be reacted with acetic acid, according to Zal'kind and Gerchikov,[32] by mild heating with 10 per cent excess of acetic acid and 0.3 per cent sulphuric acid for one-half hour. A yield of 83 per cent was obtained. Under the same conditions the sec-

ondary heptyl alcohol, methylcyclohexanol, gives 78 to 80 per cent of the corresponding ester. Acetic acid as dilute as 60 per cent was said to be satisfactory in making this preparation. Cyclohexanol and 85 per cent formic acid, when allowed to stand in the cold without catalyst for 24 hours, gave 85 to 90 per cent of the formate. The monoester of oxalic acid could not be prepared, although by refluxing cyclohexanol with the anhydrous acid, the dicyclohexyl oxalate was obtained.

ETHERS OF HIGHER SECONDARY ALCOHOLS

The method of making an ether from the corresponding alcohol, by dehydration in the presence of sulphuric acid, may be applied to the higher aliphatic ethers. Thus, Hennion, Hinton and Nieuwland[33] prepared ethers by heating the corresponding alcohols with sulphuric acid while removing water in the vapor form. Reaction was carried out until the temperature of the mixture reached a point midway between the boiling point of the alcohol and that of the ether. The latter was isolated by cooling the mixture, diluting with water, then washing with aqueous sodium hydroxide, and distilling. Other acids, such as phosphoric or benzenesulphonic, have been proposed as the dehydrating agent. To facilitate continuous removal of water during reaction, a water-immiscible entraining agent which forms an azeotrope with water having a minimum boiling point (e.g., a light gasoline fraction) may be added to the reaction mixture. In the case of *n*-butyl alcohol, however, it is said that the products form a mixture of minimum boiling point with water, making unnecessary addition of an entraining agent.[34]

As an alternative procedure, sulphuric acid solutions of olefin may be used. A continuous process has been described,[35] in which such acid liquors are hydrolyzed with water and distilled. That portion of the distillate consisting of alcohol and water is returned to the hot acid liquor for further dehydration.

It has been reported,[36] however, that the higher ethers (those from alcohols having more than 7 carbon atoms per molecule) may be produced in alkaline media. The starting materials in this instance are sulphuric or phosphoric acid esters of the alcohol, which are heated with the alcohol or a phenol, in alkaline media, or with alcoholates or phenolates.

INDUSTRIAL APPLICATIONS OF SECONDARY BUTYL ALCOHOL

Ellis[37] finds that *sec*-butyl alcohol may be used as an homogenizer in the preparation of a nitrocellulose coating composition. A low viscosity nitrocellulose is dissolved in 40 parts of diacetone alcohol, 30 parts of a cracked petroleum distillate (boiling between 70° and 120°C.) as a diluent and viscosity reducer, and 30 parts of *sec*-butyl alcohol. A compatible synthetic resin may be incorporated, or if a colored lacquer is to be produced, a pigment may be ground in with the solvents. Such liquid compositions may be applied over varnish coatings without dissolving and disintegrating the undercoat.

As has been stated, the characteristic oxidation reaction of the secondary alcohols leads to the production of ketones.[38] However, certain methods of oxidation

[38] Such reactions are discussed in Chapter 18.

give rise to acids containing fewer carbon atoms. Thus, Pelton and Kennedy[39] suggest that *sec*-butyl alcohol be reacted with a fused mixture of potassium and sodium hydroxides at 200°-325°C. to give propionic acid. Strosacker, Kennedy and Pelton[39a] report that *sec*-butyl alcohol and propyl alcohol may be mixed and subjected to the action of fused caustic soda to obtain alkali propionates.

Hardy[40] has reported another type of reaction producing acids or their esters. *sec*-Butyl alcohol was condensed at 200°C. to 210°C. with carbon monoxide in the presence of phosphoric acid containing a small amount of copper phosphate. From one kilogram of the alcohol, about 29 grams of the methyl ester of pivalic (trimethylacetic) acid and 10.5 grams of the methyl ester of methylethylacetic acid resulted.

Among the uses for which the secondary alcohols have been suggested is included the production of esters. Much work has been done in consequence, with a view to facilitating and improving the processes used in extracting water from the alcohols, and for increasing the purity of the product. In procedures designed to render the alcohol anhydrous, some care must be taken that it is not dehydrated to the olefin, though the secondary alcohols, as compared with the tertiary, are fairly stable in this respect. As pointed out before, the higher alcohols are only slightly soluble in water, nor are large proportions of water soluble in the alcohols. Those of the octyl and nonyl range are not ordinarily contaminated by large quantities of water, but neither have they so far become of industrial importance. The greatest interest has centered on the secondary butyl and amyl alcohols. The majority of methods proposed for rendering these anhydrous depend on the use of entraining agents or solvent extraction, and frequently both. Taylor[41] suggested that carbon tetrachloride be used as an agent for drying the higher alcohols. The alcohols may first be extracted with carbon tetrachloride, whereby a large proportion of the water present is eliminated. That taken up in the extract can then be removed by distillation as a ternary azeotrope with carbon tetrachloride and alcohol. Finally, methyl alcohol is added, and the carbon tetrachloride and methanol removed as a binary azeotrope. If the secondary alcohol does not form a low boiling azeotrope with carbon tetrachloride, or a ternary azeotrope with the tetrachloride and water, the latter is removed in a water-carbon tetrachloride mixture which boils out at 66°C. Shiffler and Mithoff[42] have used a light petroleum ether in an analogous manner. In this case the liquid to be dried (such as *sec*-butyl alcohol) is passed into a stratifying zone, where it is brought in contact with the condensate obtained from a latter stage of the process. This condensate consists of portions of the *sec*-butyl alcohol, water, and petroleum ether. The petroleum ether brings about a separation, acting as solvent for the alcohol, and two layers are formed, one relatively rich in the butanol, and poor in water, while most of the water and a small amount of alcohol form the lower layer. The petroleum layer is passed to a reflux condenser. The vapors from this column are condensed and used in the first step of the process, recirculating through the system in this way.

Lebo,[43] on the other hand, proposes distilling the water and alcohol to a constant-boiling mixture without addition of entraining agents, eliminating the solvent extraction step. Thus, *sec*-butyl alcohol may be distilled to the constant-boiling point, and this distillate collected. A second distillation is then carried out, after adding an entraining agent such as benzene or xylene.

For the removal of aldehyde impurities that may be present in primary alcohols, Burke[44] suggests a treatment involving refluxing with an amine so chosen that the boiling point of the alcohol being treated is more than 15°C. removed from the boiling point of the amine. The alcohol is distilled in a column into which an amine is admitted at a point near the top (but not at the top, lest the product be contaminated) so that it flows down counter to the ascending vapors. Such amines as aniline, phenylacetyl amine or naphthylamine may be used. Other contaminants, such as mercaptans which impart color and objectionable odor, may be removed by using an aqueous sodium plumbite washing solution.[45]

INDUSTRIAL APPLICATIONS OF THE ESTERS OF SECONDARY BUTANOL

The most important ester of secondary butyl alcohol is the acetate, which is made on a considerable scale.[46] One method suggested for this synthesis[47] proposes that the alcohol and the organic acid be heated together in the presence of a catalyst until equilibrium is reached. The mixture is fractionally distilled, and the condensate allowed to stratify. The water and *sec*-butyl acetate produced are removed in equivalent proportions, and the remainder returned to the column as reflux. Further alcohol and acid are added to compensate for the product extracted. Merley[48] states that the product of esterification may be freed from impurities, such as mercaptans and hydrocarbons, by a system of successive distillations. First, a fractional distillation of the material is carried out, eliminating the major portion of the impurities present. The rectified portion is then redistilled with the addition of water. The product of this last step is finally redistilled to eliminate water. Merley[49] has also pointed out that the small amounts of tertiary esters which may be present (e.g., *ter*-butyl acetate) may be removed by heating with an aqueous solution of a mineral acid (such as sulphuric acid) containing the acid of the ester (in this case, acetic acid). The tertiary ester is decomposed completely, and the more stable secondary ester may be recovered by fractional distillation.

The secondary acetate is finding widespread use as a lacquer solvent and thinner. Blech[50] has suggested the use of *n*-butyl acetate in a hand-cleaner capable of removing lacquer, varnish, printer's ink and similar materials. The composition consists essentially of a soap, water, diatomaceous earth, glycerine and a perfumed detergent and scouring compound, to which a rapid-acting volatile solvent such as *n*-butyl acetate is added to dissolve rapidly the lacquer material present. Wilson[51] proposes that *sec*-butyl acetate be used in the dewaxing of oil. The latter is mixed with the ester, is agitated with a solvent, the solution subsequently cooled and the precipitated wax removed by filtration.

Butyl formate has been found to be definitely toxic, and may be used as an insecticide. Bass and Fenn[52] report that *sec*-butyl lactate may be produced by reacting the anhydrous acid and the secondary alcohol in a reaction bomb. The temperature is raised to 170-175°C., and the reactants maintained at this temperature under pressure for 4 hours. The resultant ester is purified by fractional distillation.

HIGHER SECONDARY ALCOHOLS

The higher secondary alcohols may be produced by the sulphation process, but those originating from olefins above the heptene range are prepared in lesser quantities in this manner. The most important of the alcohols above *sec*-butanol are *sec*-amyl and *sec*-hexyl, which are made commercially in considerable volume. They have been suggested as solvents in the ozocerite refining process proposed by Cox.[53] The crude ozocerite is agitated with a liquid consisting of 80 per cent *n*-butanol and 20 per cent *sec*-amyl alcohol. The waxy constituents are taken into solution by this alcoholic mixture, while the asphaltic fractions remain suspended in the liquid medium. The process is carried out at a temperature above the melting point of the wax, until the wax solution and the asphaltic particles are thoroughly emulsified. Rapid cooling then causes the waxy constituents to precipitate from solution, carrying the asphaltic material down with them. Heating the mixture subsequently without agitation, redissolves the wax, which can then be separated from the insoluble asphaltic residue. It has also been suggested[54] that the high molecular weight alcohols obtained from olefins are capable of stabilizing a suspension of metal soaps in mineral oils. Relatively small proportions of these heavier alcohols are reported to be sufficient.

The esters of *sec*-hexyl, -heptyl and -octyl alcohols and dicarboxylic acids (such as dioctyl phthalate) may be used as plasticizers with cellulose nitrate, Van Schaack[55] reports. Mixed esters involving lower alcohols as well as these higher secondary compounds may be used.

A number of alkylated benzene homologs and derivatives have been made from the higher secondary alcohols.[56] Austin[57] states that alkyl resorcinols may be prepared by condensing a secondary alcohol (such as heptanol-2) with resorcinol in the presence of a condensing agent. Schrauth[58] reports that interaction of *sec*-amyl alcohol with naphthalene can be carried out in the presence of sulphuric acid to produce a wetting and cleansing agent. Naphthalene sulphonic acid may be used in place of the hydrocarbon. Thus, 600 parts of naphthalene may be converted into naphthalene sulphonic acid by treatment with 720 parts of sulphuric acid at 110° to 180°C. The reaction mixture is cooled to 105°C. and maintained at this temperature while a solution of 620 parts of *sec*-amyl alcohol and 40 parts of sulphuric acid is added over a period of four hours. The mixture is then heated to 125°C. for four more hours. The mass separates into two layers, the lower of which, consisting of sulphuric acid, is withdrawn. From the upper layer, the unaltered sulphuric acid is removed by treatment with lime. The solution of amylated naphthalene sulphonic acid so obtained is neutralized with sodium carbonate to form the sodium salt. The latter is said to be a wetting emulsifying or lathering agent. *sec*-Amyl alcohol may be substituted by cyclohexanol or methylcyclohexanol.

PROPERTIES OF THE TERTIARY ALCOHOLS

Dehydration of tertiary alcohols differentiate them even more sharply than do the analogous reactions of secondary alcohols, and it is difficult to distil the former compounds from acid liquors without this decomposition occurring.[59] Also esters of tertiary alcohols are hydrolyzed readily. Due to their structure, oxidation of this type of alcohols cannot lead to the production of aldehydes or ketones of the same number of carbon atoms. The tertiary alcohols are, however, more reactive in such instances as the alkylation of aromatic hydrocarbons, probably because of the ease with which they are dehydrated to the corresponding highly reactive tertiary olefin, which acts as an intermediate.

Some of the physical properties of certain tertiary alcohols are given in Table 98.

TABLE 98.—*Some Higher Tertiary Aliphatic Alcohols.*[60]

Alcohol	Boiling Point °C.	Melting Point °C.	Density 20/4°C.

Not only dehydration of tertiary alcohols, but also the converse reaction, i.e., hydration of tertiary olefins, is catalyzed by the presence of acids. Lucas and Liu[61] have studied the comparative effectiveness of a series of acids in promulgating the hydration of such olefins, and report that comparatively dilute acid solutions show considerable catalytic power. Thus, one-tenth molar solutions of several acids tested were found to be efficacious, though activity decreased in the order, dithionic, sulphuric, hydrochloric, hydrobromic, nitric, *p*-toluenesulphonic, picric, oxalic, and acetic acid. Even the weaker organic acids such as formic, oxalic and acetic are known to promote hydration of tertiary olefins in dilute aqueous solution.

Dehydration of tertiary alcohols in the presence of dilute sulphuric acid is a method suggested for the preparation of pure tertiary olefins. Deanesly and Engs[62] report producing pure isobutene by heating the corresponding tertiary alcohol with aqueous sulphuric acid at a temperature of 70° to 85°C., and maintaining the alcohol concentration constant by feeding *ter*-butanol at a rate equivalent to that of olefin formation. Thermal decomposition of *ter*-butyl or *ter*-amyl alcohol appears to be largely dehydration, Schultz and Kistiakowsky[63] find. Experiments conducted using quartz bulbs at 480° to 550°C. indicated the reaction was homogeneous and unimolecular.

Polymerization and co-polymerization are important side reactions in the dehydration of the tertiary alcohols. Whitmore and Mixon[64] report that the action of 65 per cent sulphuric acid on an equimolar mixture of tertiary butyl and tertiary amyl alcohols yielded products containing over 69 per cent of polymerized hydrocarbons. Of the latter, 17 per cent were nonenes resulting from condensation of the pentenes and butenes formed during dehydration. They were identified as chemical individuals by ozonolysis and fractionation of the products, and were found to be 1,2,3,3-tetramethylpentene-1 (50 per cent), 3,3,5-trimethylhexene-2 (23 per cent), 2,4,4-trimethylhexene-2 (10 per cent), 2,3,4,4-tetramethylpentene-2 (10 per cent), 2,2,4-trimethylhexene-3 (5 per cent). The two other isomers, 2,4,4-trimethylhexene-1 and 2-ethyl-4,4-dimethylpentene-1, were not found in the products.

Certain tertiary alcohols containing the neopentyl (2,2-dimethylpropyl) group have been found by Whitmore and Laughlin[65] to be readily dehydrated (without rearrangement) under the influence of naphthalene-β-sulphonic acid or iodine. However, in certain cases dehydration is followed by fission and profound isomerization. If 2,2,3,4-tetramethylpentanol-3 is distilled with a small proportion of iodine, it is transformed into 2-isopropyl-3,3-dimethylbutene-1, Nazarov[66] reports. The latter compound, in the presence of 1-bromonaphthalene-4-sulphonic acid, is transformed into 2-methylpropene-1, and 2-methylbutene-2. Treatment of 3-ethyl-2,2,4-trimethylpentanol-3 with iodine yields 4,4-dimethyl-3-isopropylbutene-2, which in turn may be converted by 1-bromonaphthalene-4-sulphonic acid into 2-methylpropene-1, 2-methylpentene-2 and 2-methylpentene-1. This investigator[67] has also observed the dehydration of methyl-di-*ter*-butylcarbinol (2,2,3,4,4-pentamethylpentanol-3) by slow distillation in the presence of iodine. A mixture of olefins was obtained, consisting largely of di-*ter*-butylethylene. This latter compound heated with bromonaphthalenesulphonic acid at 180°C. yielded *ter*-butylethylene, *asym*-methylisopropylethylene, and tetramethylethylene.

Reaction with Aromatics. As previously indicated, tertiary alcohols react vigorously with benzene and benzene homologues under the influence of condensing agents, either those such as strong mineral acids or of the Friedel-Crafts type. The products consist largely of *ter*-alkylated aromatic hydrocarbons. Tzukervanik[68] has noted that compounds of the type $AlCl_2(OR)$ are first formed, and these are decomposed in the presence of excess aluminum chloride or on heating to yield the corresponding olefins and alkyl chlorides. Alkylation is considered by Tzukervanik to proceed according to the consecutive reactions:

$$\begin{aligned} ter\text{-}C_4H_9OH + AlCl_3 &\longrightarrow AlCl_2(OC_4H_9) + HCl \\ AlCl_2(OC_4H_9) &\longrightarrow C_4H_8 + AlCl_2(OH) \\ C_4H_8 + HCl &\longrightarrow C_4H_9Cl \\ C_6H_6 + C_4H_9Cl &\longrightarrow C_6H_5 \cdot C_4H_9 + HCl \end{aligned}$$

By condensing *ter*-butyl or amyl alcohols with benzene or toluene in the presence of aluminum chloride, alkylated hydrocarbons may be obtained in 50 to 70 per cent yields. In this way such compounds as *ter*-amylbenzene, *ter*-amyltoluene, *ter*-butylbenzene and *ter*-butyltoluene were prepared.

Using sulphuric acid as the condensing agent, Barbier[69] reports that isopropylbenzene and *ter*-butyl alcohol furnished isopropyl-*ter*-butylbenzene (boiling at 221°C.). This investigator also reports that a *ter*-butylcymene boiling at 220 to 230°C. may be formed by the reaction between cymene and *ter*-butyl alcohol in the presence of sulphuric acid below 0°C. The product is recovered by diluting the reaction mixture with ice water, separating the hydrocarbon layer, and fractionating.

Reaction with Phenols. Tzukervanik and Nazarova[70] find that the condensation of phenols and tertiary alcohols yields largely alkylphenols (and not phenol ethers as in the case of secondary alcohols) while small amounts of olefins and alkylated aromatic hydrocarbons are formed as by-products. *ter*-Butyl alcohol and phenol in light petroleum ether were treated with aluminum chloride to obtain 75 per cent yields of *ter*-butylphenol. Increased amounts of aluminum chloride favored the production of increased quantities of alkylated phenols. As with the benzene homologues, the phenols may be condensed with tertiary alcohols in the presence of strong mineral acids. The products obtained by absorption of olefins in moderately concentrated acid may be directly condensed with phenols, Thomas[71] reports. This investigator prepared *ter*-amylphenol by absorbing *iso*amylene in 62 per cent sulphuric acid, and agitating the resulting liquor for 1 hour with 75 per cent excess of phenol. The oily layer was separated, and refluxed for four hours at 130° to 135°C., then washed with water, neutralized and distilled. Chichibabin[72] noted that the use of phosphoric acid as a condensing agent causes the formation of ortho-alkylated phenols almost exclusively. Using phosphoric acid (*d* 1.83 to 1.85) as a condensing agent, *m*-cresol and *ter*-butyl alcohol yielded *o*-*ter*-butyl-*m*-cresol.[73]

Esters of the Tertiary Alcohols

Esters of tertiary alcohols are not readily produced by direct esterification of the alcohol with carboxylic acids. In the presence of sulphuric acid, for example, the yield of *ter*-butyl acetate from *ter*-butyl alcohol and acetic acid is only about 24 per cent of the theoretical, although better results have been obtained by the use of an aqueous solution of hydrogen sulphide as catalyst. Norris and Rigby[74] reported that good yields could be obtained by refluxing the alcohol with acetic anhydride and a small amount of zinc dust. When treated with acetyl chloride, *ter*-butyl alcohol gives about equal quantities of the acetate and the chloride. However, the acetate is practically the only compound obtained if the acid chloride and alcohol are reacted in the presence of dimethylamine. On the other hand, in the absence of the amine, at temperatures below 20°C., a quantitative yield of the chloride is secured.

Tertiary alkyl esters of organic acids may be prepared by the direct esterification of the appropriate olefin, as described in Chapter 12. However, these esters as yet have found little industrial application, probably because of the ease with which they undergo hydrolysis.

Hughes[75] reported a study of the hydrolysis of *ter*-butyl chloride in aqueous alcohol or acetone. With the alkyl halide in large excess, the velocity of reaction in dilute alkaline solution was constant, and independent of the concentration of alkali, continuing at the same rate even after the alkali was neutralized and the liquid medium became acid. In the presence of a slight excess of potassium hydroxide, the reaction rate is independent of the alkali concentration, and equal to that determined in the complete absence of alkali. In dilute solutions, the reaction velocity is independent of the concentration of the alkyl halide, but at higher concentrations its value shows a marked increase. In ethyl alcohol solutions, the presence of water has a very strong influence. In 90 per cent ethanol the value of the reaction constant is 0.00616, but in 40 per cent ethanol it rises to 4.66. Temperature, too, greatly affects the rate of dissociation. In 80 per cent ethyl alcohol the value of the constant increases from 0.0031 at 8°C. to 0.380 at 45°C.

Carre and Libermann[76] state that the alkyl chlorosulphites (of the formula ROSOCl) may be prepared by adding the alcohol to a 10 to 20 per cent excess of thionyl chloride, and allowing the mixture to stand at room temperature for 48 hours. Although the *sec*-butyl chlorosulphite was prepared and distilled, the *ter*-butyl compound was too unstable to permit of distillation.

French, McShan and Johler[77] observed that treatment of tertiary bromides with hydroxides of silver, barium or those of the alkali metals yielded only small proportions of olefins, alcohol being the main product. Woodburn and Whitmore[78] state that the tertiary halides are more resistant to hydrolysis than is ordinarily supposed. Although the tertiary chlorides with hot water or hot sodium carbonate solution yield the corresponding olefin exclusively, with cold water or cold sodium carbonate, a certain amount of tertiary alcohol is formed together with the unsaturated hydrocarbon. The physical properties of some of the *ter*-butyl esters are listed in Table 99.

ETHERS OF TERTIARY ALCOHOLS

According to Norris and Rigby,[79] the mixed ethers of tertiary alcohols, such as *ter*-butanol, may be prepared in fairly good yield, using sulphuric acid or aqueous sodium hydrogen sulphate as catalyst. These investigators added one mole of the tertiary alcohol to a boiling mixture of two moles of ethyl alcohol and a 15 per cent solution of sulphuric acid, the volume of which was about two and a half times that of the ethyl alcohol. The minimum boiling mixture of the ether and water was distilled from the reaction mixture. A yield of 95 per cent of the mixed ether was reported. The reaction of *ter*-butanol with a secondary alcohol (isopropanol) required a different catalyst, since the alcoholic hydrogen of secondary alcohols, as already indicated, is less reactive than that of the primary carbinols. Therefore, a greater molecular proportion of isopropyl alcohol was employed, and as catalyst, sodium hydrogen sulphate was employed instead of the acid, in order to prevent formation of isobutene by dehydration of the *ter*-butanol. In this way a yield of 82 per cent of *ter*-butyl-*sec*-propyl ether was obtained.

[79] J. F. Norris and G. W. Rigby, *loc. cit.*

It was found that these tertiary ethers are highly reactive. When *ter*-butylethyl ether was allowed to stand in contact with concentrated hydrochloric acid, the former was rapidly converted (to the extent of 99 per cent) into *ter*-butyl chloride. The reactivity of the tertiary ether as compared to the corresponding normal ether is illustrated by the time of reaction of the two ethers with hydrochloric acid. The normal butylethyl ether reacts with hydrochloric acid to give a 25 per cent conversion in 768 hours at 25°C. The tertiary ether corresponding gives a 25 per cent yield of *ter*-butyl chloride in 0.83 hour, at 0°C.

Evans and Edlund[80] report a method of producing the tertiary ethers of polyhydric alcohols such as ethylene glycol by the reaction of the corresponding olefin with the alcohol. Mineral acids, or metallic salts serve as catalysts. These investigators find that in general the tertiary alkyl ethers of monohydric alcohols are relatively insoluble in water, form peroxides only slowly, and are stable in alkaline but not in acid solutions. Those derived from polyhydric alcohols are relatively soluble in water. These ethers have been suggested as entraining agents, solvents or diluents in lacquer and varnish preparations.[81]

The physical properties of some of the mixed tertiary ethers, as given by Evans and Edlund, are listed in Table 100.

TABLE 100.—*Mixed Tertiary Alkyl Ethers.*

Ether	Boiling Point, °C.	d_4^{20}
Methyl *ter.*-butyl	55	0.7405
Ethyl *ter.*-butyl	73	0.7404
Isopropyl *ter.*-butyl	87-88	0.742
n-Butyl ter.-butyl	123-124	0.7615
Isobutyl *ter.*-butyl	114	0.7516
sec.-Butyl *ter.*-butyl	114-115	0.7604
Isoamyl *ter.*-butyl	138-140	0.7662
Methyl *ter.*-amyl	86-87	0.7703
Ethyl *ter.*-amyl	101-102	0.7657
Isopropyl *ter.*-amyl	114-115	. . .
Methyl *ter.*-hexyl	113	0.7815
ter.-Monobutyl ether of ethylene glycol	153	0.8970
ter.-Dibutyl ether of ethylene glycol	171	0.8266
Mixed methyl *ter.*-butyl ether of ethylene glycol	131-132	0.8399
Mixed ethyl *ter.*-butyl ether of ethylene glycol	148	0.8311
Mixed *n*-butyl *ter.*-butyl ether of ethylene glycol	83 (20 mm.)	0.8317
ter.-Monobutyl ether of 1,2-propene glycol	151-153	0.8707
ter.-Monobutyl ether of glycerol	93-94 (5 mm.)	0.9947
ter.-Dibutyl ether of glycerol	80-82 (4 mm.)	0.8921
ter.-Monoamyl ether of ethylene glycol	50-55 (3 mm.)	0.8993
ter.-Monobutyl ether of diethylene glycol	72 (2 mm.)	0.9374
Phenyl *ter.*-butyl	185-186	0.9214
Benzyl *ter.*-butyl	82-83 (8 mm.)	0.921

USES OF TERTIARY BUTYL ALCOHOL

Ellis[82] has pointed out the applicability of *ter*-butyl alcohol in solvent refining processes to free oils of wax and asphalt. Thus, a pressing distillate obtained from a Pennsylvania crude oil was mixed at room temperature with half its volume of *ter*-butyl alcohol. The mixture was then cooled to 5-10°C. On remaining at this temperature for some time, a voluminous precipitate was formed, consisting principally of wax, which could be separated from the alcohol-oil solution by filtration. The clear filtrate was further separated into oil and alcohol by distillation. A quantity of heavy bottoms (obtained by the distillation of a Mid-Continent crude oil to about 20 per cent of bottoms), containing both wax and asphalt was mixed with *ter*-butyl alcohol. An alcohol-oil ratio of about 5 to 1 was used with this heavy material, and the mixture was heated to 35-40°C. to secure complete solution of the oil in the alcohol. During heating the mixture was well agitated. The asphaltic content did not entirely dissolve under these conditions, but some separated in the form of small globules which coalesced, particularly on cooling, to form a tarry mass. The alcohol containing the oil was decanted after cooling to somewhat below room temperature. The alcohol solution was further cooled to 5-10°C. to precipitate wax, and the alcohol and oil separately recovered by distillation.

[82] Carleton Ellis, U. S. P. 2,062,355, Dec. 1, 1936 to Standard Oil Development Co.; *Chem. Abs.*, 1937, **31**, 849. See also British P. 450,511, 1936, to Bataafsche Petroleum Maatschappij; *Chem. Abs.*, 1937, **31**, 249; French P. 801,026, 1936, to Bataafsche Petroleum Maatschappij; *Chem. Abs.*, 1937, **31**, 250.

The cooling step may be carried to a lower temperature, if desired, to secure further separation of wax. However, if the temperature is made too low, the rather easily frozen *ter*-butyl alcohol will solidify. This is not harmful, it is said, unless carried to an extreme, as a slight deposit of alcohol crystals may serve as an aid in forming a filtering network of crystals. The separation of the mixed alcohol and wax crystals may be brought about by allowing the material to warm up to the melting point of the alcohol and filtering off the wax.

By the addition of a small quantity (5 per cent) of water to a solvent composed of 80 per cent *ter*-butyl alcohol and 20 per cent *ter*-amyl alcohol, separation can be made to occur when the solution is cooled. When a Colombian lubricating distillate was treated with this mixed solvent, and heated to 65-70°C. and at the same time thoroughly agitated, solution took place. However, when the batch was permitted to cool to room temperature, a sharp separation occurred, forming two layers. The lower (oil) layer was withdrawn, and the dissolved solvent separated by distillation. Distillation of the upper layer permits separation of the alcohol and extract.

A mixture of propene chloride and *ter*-butyl alcohol has been proposed as a solvent for cellulose acetate. Taylor[83] states that a composition containing these substances can be used in forming flexible sheets of cellulose acetate.

Parks, Warren and Greene[84] have found that *ter*-butyl alcohol may be used satisfactorily in molecular weight determinations by the Beckmann freezing point method. The hygroscopic character of the solvent and its tendency to undercool must be taken into consideration in the manipulations, but these difficulties may be overcome by using a freezing tube stopped against moisture from the air by means of rubber tubes. Undercooling was overcome by sealing a small platinum wire into the lower end of the tube. When making determinations, this wire was touched from time to time with a soldering copper which had been cooled on solid carbon dioxide, giving a small deposit of crystals on the surface of the wire from which crystallization would proceed.

The alcohol with which the work was done was a commercial product (originally freezing at 20°C.) which had been fractionally distilled twice over lime and was then subjected to ten fractional crystallizations. The final product melted at 25.4°C. By thermodynamic calculations the cryoscopic constant was determined as approximately 8.27. Experimental work on freezing mixtures in dilution such as to lower the freezing point of the mixture by one degree gave the cryoscopic constant $K = 8.30$ in the equation

[83] E. R. Taylor, U. S. P. 2,000,622, May 7, 1936, to Eastman Kodak Co.; *Chem. Abs.*, 1936, **30**, 4175; *Brit. Chem. Abs.* **B**, 1936, 588.

[84] G. S. Parks, G. E. Warren and E. S. Greene, *J.A.C.S.*, 1935, **57**, 616; *Brit. Chem. Abs.* **A**, 1935, 699; *Chem. Abs.*, 1935, **29**, 3217.

$$M = 1000\,K(g/G\Delta T_f)$$

where M is the molecular weight of the solute, K the cryoscopic constant of the solvent, g the number of grams of solute in solution, G the number of grams of solvent, and ΔT_f the difference between the original freezing point of the *ter*-butyl alcohol (25.4°C.) and the freezing point of the particular solution being tested.

The experimental values for the molecular weights of various solutes were determined with reasonably satisfactory accuracy except in the cases of isopropyl alcohol (error of +23.1 per cent), *sec*-butyl alcohol (+16.5 per cent), *ter*-amyl alcohol (+90.9 per cent), phenol (−3.7 per cent) and *p*-toluidine (−4.7 per cent). In the case of phenol, the observed error may be due to the formation of a compound with the alcohol. The *p*-toluidine on the other hand was not entirely pure. In the cases of the three alcohols, it was shown that mixed crystals were being formed. The equation given above does not apply in the latter instance which is, apparently, the source of anomalous results. However, the method was found applicable to all classes of hydrocarbons, and most types of organic compounds, including the primary alcohols. (With ethylbenzene, the percentage error was −0.4 per cent. With *o*-xylene, no error was found.)

One of the most important reactions of the tertiary alcohols involves their condensation with phenols and benzene derivatives in the presence of a condensing agent such as aluminum chloride, zinc chloride, or phosphoric or sulphuric acid. A tertiary alkyl phenol may be prepared, thus, by reacting *ter*-butyl alcohol with phenol in the presence of aluminum chloride at about 30°C.[85] Langwell[86] reports a similar condensation using zinc chloride as the condensing agent. He proposes, however, that the temperature of the reaction can be controlled by having present a volatile liquid which boils at a temperature somewhat lower than the operating temperature (about 130°C. in case of tertiary alcohols. A similar condensation of primary alcohols requires a temperature of 180°C.) Interaction may be effected by adding the volatile liquid (e.g., isohexene or benzene), phenol, and alcohol to a solution of zinc chloride, and heating under reflux. Chichibabin[87] used phosphoric acid in effecting combination of *ter*-butyl alcohol and *o*-cresol. The alcohol, *o*-cresol and phosphoric acid were heated together at 50°C. to produce *o*-*ter*-butyl-*m*-cresol. Maschmeijer and Takens[88] reacted *m*-cresol methyl ether with *ter*-butyl alcohol in 2 to 4 times its volume of sulphuric acid of 85 to 95 per cent strength at lower temperatures (20°C. or less) to obtain 1-methyl-3-methoxy-4-*ter*-butylbenzene. Barbier[89] states that very little sulphonation takes place in the alkylation of cymene with *ter*-butyl alcohol in the presence of sulphuric acid if the temperature is kept below 0°C. Afterwards, separation of the reacted compounds may be obtained by adding ice water, to form an oily layer containing the *ter*-butylcymene. The latter substance may be recovered by fractionating the products and collecting the portion boiling at 220° to 230°C. It is said that a good yield of a material which is entirely nitratable to dinitro-*ter*-butylcymene is obtained.

[89] H. Barbier, U. S. P. 1,951,123, March 13, 1934; *Chem. Abs.*, 1934, **28**, 3426; *Brit. Chem. Abs.* B, 1935, 182.

Van Schaack[90] states that a mixture of 30 volumes of *ter*-butyl alcohol and 70 volumes of gasoline displayed better antiknock properties than did a 30-70 blend of benzol and gasoline. The use of the butyl alcohol in this manner is said to have advantages over the analogous utilization of ethanol, in that the four-carbon-atom alcohol has a higher fuel value, while its boiling point and volatilization characteristics closely resemble those of the lighter alcohol (ethanol). Deanesly[91] has proposed that the alcohols formed by absorbing olefins in sulphuric acid be extracted in an organic solvent immiscible with the acid, and the solution of alcohols so produced used directly as an antiknock fuel, or as a solvent. It has been suggested that *ter*-butyl alcohol alone be used as a fuel for racing motor cars or airplane engines. In such instances it may be mixed with as much as 30 per cent water, or may contain polymers of olefins, for example the dimer of 2-methylpropene, the dehydration product of *ter*-butanol.[92]

Birch, Pim and Tait[92a] suggest that the high antiknock value of isoolefins may be accounted for indirectly through the medium of tertiary alcohols. They find that the action of concentrated sulphuric acid on a mixture of tertiary amyl and butyl alcohols (derived from the corresponding lower olefins) gives good yields of the polymers. 2,2,4-Trimethylpentane, the octane commonly employed in octane rating, was produced by this type of condensation and subsequent hydrogenation. Several other fractions were obtained showing octane ratings as high as 98 to 100.2.

In numerous applications, particularly in producing blended fuel containing the alcohol, a dry *ter*-butyl alcohol is desirable. Hartmann[93] finds that liquids of this character may be rendered anhydrous by distillation with phthalic anhydride. He observes that the anhydride combines preferentially with water and any primary butanol that may be present, while the tertiary alcohol may be recovered by distillation. The resulting phthalic acid may be dehydrated and reused.

Becker and Muller[94] report that wetting, frothing and emulsifying agents may be produced from tertiary alcohols by treatment with concentrated sulphuric acid. In the suggested process, 500 parts of tertiary alcohol (e.g., *ter*-butanol) are mixed with 500 parts of concentrated sulphuric acid, while cooling. The mixture is then heated on a water bath, and in the course of two hours, separation occurs. The oily layer is withdrawn and reacted with a strong sulphonating agent, such as chlorosulphonic acid. The resulting sulphonated polymerized hydrocarbons are said to have wetting properties, either when used as the sulphonic acids or in the form of their sodium salts.

USES OF TERTIARY ESTERS AND ETHERS

Norris and Rigby[95] state that reaction between *ter*-butyl alcohol and concentrated hydrochloric acid proceeds more than 200,000 times as rapidly as that between the primary alcohol and the acid. It appears from their work that the hydroxyl group of the tertiary alcohols is much more reactive than that of the primary or even secondary alcohols. The alcoholic hydrogen, however, is not as reactive as that of the corresponding atom in the normal butanol. For example, metallic sodium and *ter*-butyl alcohol interact slowly and the sodium *ter*-butylate formed combines very slowly with alkyl halides to give ethers. When the tertiary alkyl halides are treated with sodium derivatives of normal alcohols, the result is mainly the elimination of hydrogen chloride from the tertiary halide.

[94] L. Becker and R. Muller, U. S. P. 1,950,287, March 6, 1934; *Chem. Abs.*, 1934, **28**, 3626; *Brit. Chem. Abs.* B, 1935, 93.

[95] J. F. Norris and G. W. Rigby, *J.A.C.S.*, 1932, **54**, 2088; *Chem. Abs.*, 1932, **26**, 3229; *Brit. Chem. Abs.* A, 1932, 718.

Deanesly,[96] however, has reported that the tertiary alkyl hypohalites can be prepared by a direct process. Equimolar proportions of the alcohol (e.g., *ter*-butanol) and sodium hydroxide are treated with the halogen (bromine or chlorine) in the presence of sufficient water to form a two-phase system.

Putnam, Britton and Perkins[97] describe the condensation of tertiary alkyl halides with phenols in the presence of aluminum chloride. Thus, they observe that *p*-*ter*-butylphenol may be formed by the interaction of a phenol (having the para-position free) and *ter*-butyl chloride at a temperature between 20 and 50°C. in the presence of aluminum chloride. A liquefying solvent such as phenol which will not unite with the substances involved to form undesirable by-products is said to aid the reaction. Perkins, Dietzler and Lundquist[98] used an analogous reaction for the preparation of 2,4-di-*ter*-butylphenol as well as the 4-*ter*-butylphenol and a small yield of 2-*ter*-butylphenol. Thus, if *ter*-butyl chloride is heated with an equimolar amount of phenol and 0.5 per cent of aluminum chloride at 90°C., 70.2 per cent of 4-*ter*-butylphenol, 7.1 per cent of 2,4-di-*ter*-butylphenol and 1.2 per cent of 2-*ter*-butylphenol are obtained.

Evans and Edlund[99] suggested the employment of mixed tertiary ethers in extracting and concentrating various organic carboxylic acids. They propose that such acids as formic, acetic, propionic or butyric could be freed from inorganic acid content by azeotropic distillation with methyl-*ter*-amyl ether, methyl-*ter*-butyl ether, or a homolog. The ether should be so chosen that it boils at a temperature higher than the boiling point of the acid under treatment.

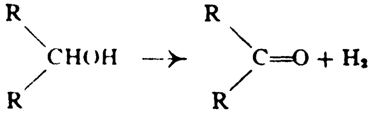
Chapter 18

Production, Properties and Uses of Ketones Derived from Alcohols and from Hydrocarbons

The lower aliphatic ketones, particularly acetone and methyl ethyl ketone, find application in many branches of chemical technology, notably as solvents and as raw materials in the synthesis of organic chemicals and resins. Both saturated and unsaturated hydrocarbons may be converted into ketones by several types of single-stage process which do not involve the intermediate formation of alcohols. In general, however, ketones are produced from secondary alcohols through the removal of two atoms of hydrogen from the latter either by dehydrogenation or by oxidation. This may be represented by



$$R_2CHOH \longrightarrow R_2C{=}O + H_2$$

where *R* represents an alkyl or cycloalkyl group.[1]

PRODUCTION OF KETONES FROM SECONDARY ALCOHOLS

The conversion of secondary alcohols, such as isopropanol, into ketones involves a reversible endothermic reaction, high temperatures favoring ketone formation. Dehydrogenation is said to be rapid at temperatures of 300°C. or above when catalysts are employed. However, the reaction may also be carried out exothermally in the presence of air or oxygen. A combination of the endothermic dehydrogenation with the exothermic oxidation process is suggested in certain instances to obtain better temperature control. Various catalysts have been proposed for the two types.

Contact agents for vapor-phase dehydrogenation of secondary alcohols at elevated temperatures include copper, lead, metallic sulphides, and the phosphides, selenides, tellurides, antimonides, arsenides and bismuthates of zinc, cadmium, nickel, cobalt, iron, aluminum, calcium and magnesium. Recommended temperatures range from 150° to 625°C.[2] A reported disadvantage in this type of reaction is the rapid deterioration of many of the catalysts on prolonged use, with consequent necessity for revivification. Also, the simultaneous occurrence of side reactions, principally dehydration of the alcohol to the corresponding olefin, reduces the efficiency of ketone formation. It is reported that certain copper alloys are superior to copper as regards length of usefulness and selective action. For example, employment of copper-zinc alloys, e.g., brass, with a reaction temperature of 370-430°C. is proposed by De Simo.[3] Metallic rhenium has been suggested as a contact agent for the dehydrogenation of isopropanol.[4] It was said that dehydrogenation of the alcohol at 400°C. furnished 85 per cent of the theoretical amount of acetone. Further, it was stated that decomposition of the ketone was inhibited by this catalyst.

[1] Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934. For a review of the technical aspects of industrial solvents, see T. H. Durrans, *J.S.C.I.*, 1935, **44**, 585; *Brit. Chem. Abs.* B, 1935, 714; *Chem. Abs.*, 1935, **29**, 5541.

[2] Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934. Copper was one of the first catalysts proposed for this type of dehydrogenation. (See Carleton Ellis, *loc. cit.*) The catalytic activity of the metal in this respect is discussed by W. G. Palmer, *Proc. Roy. Soc. London*, 1921, **99A**, 412; *Chem. Abs.*, 1921, **15**, 3923; *J.C.S.*, 1921, **120** (2), 542.

In some cases promoters are advocated for use in conjunction with catalysts. For example, in the preparation of acetone, isopropanol may be contacted at 300°C. with reduced copper on pumice and a promoter, consisting of an oxide of zinc, thorium, cerium or zirconium.[5] Lazier[6] has advocated a difficultly reducible oxide of a dehydrogenating metal (e.g., zinc oxide) to be employed as a promoter in conjunction with copper and cadmium chromites.

The dehydrating effect of such oxides as those of zinc or uranium is said to be suppressed by incorporation of a more acidic oxide or salt. For example. zinc oxide alone is said to convert isopropanol into acetone in 95 per cent yield at 400°C., but when 7 per cent of zinc sulphate is admixed with the above contact agent, the yield is raised to 99 per cent.[7]

Use of a water-soluble salt of an alkali metal, e.g., sodium carbonate or silicate, as a carrier for the dehydrogenation catalyst is said to inhibit dehydration to olefins.[8]

Liquid-phase dehydrogenation of isopropyl alcohol to acetone employing 2 to 750 atmospheres pressure and temperatures of 200-500°C. has been proposed.[9] A catalyst of chromium oxide together with the oxides of manganese or zinc is advocated. Also, it has been suggested to carry out this type of dehydrogenation in the presence of an aromatic hydrocarbon which will undergo hydrogenation during the process.[10] For example, isopropanol is heated to 250°C. under a pressure of 300 lbs. in a solution of nickel carbonate and benzene.

Catalytic oxidation of secondary alcohols with the aid of such substances as copper and silver has been frequently described, but one of the reported disadvantages is the difficulty of controlling the reaction temperature. This is a result of the exothermic nature of the oxidation as was mentioned previously. Cardarelli[11] has pointed out that the conversion of isopropanol to acetone may be effected by conducting a mixture of the alcohol and the theoretical amount of oxygen over a catalyst, such as copper, at 225-350°C. Temperature control is accomplished by employing as an exterior cooling medium a stable organic compound boiling between 225-350°C., e.g., diphenylmethane, biphenyl, diphenyl ether or naphthylamine. Further, the gases which leave the reaction chamber are employed to preheat the entering isopropanol and oxygen to the reaction temperature. See

Fig. 108. On the other hand, Woolcock[12] produced acetone by oxidation of an azeotropic mixture of isopropanol and water with air. In the procedure, 63.5 g. of the binary mixture are conducted, together with 1.78 cu. ft. of air, over silver gauze. During the time of contact the reactants are maintained at 656°C.

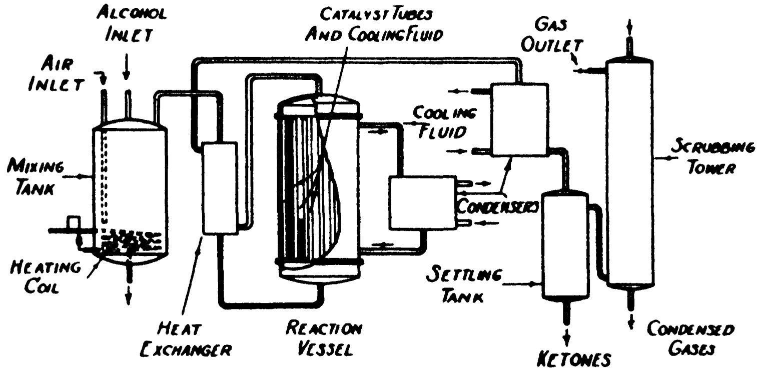

FIG. 108.—Diagram of Apparatus for Catalytic Oxidation of Secondary Alcohols to Ketones. (E. J. Cardarelli)

PRODUCTION OF KETONES FROM PRIMARY ALCOHOLS AND THEIR DERIVATIVES

A number of processes have been developed whereby primary alcohols, such as ethanol, as well as certain derivatives of such alcohols (including aldehydes, ethers and esters) are converted into ketones by catalytic treatment, usually in the vapor phase, at high temperatures.

The mechanism of the conversion of ethanol into acetone by reaction with steam has been examined by Kagan and his co-workers,[13] who consider that ethyl acetate is an important intermediate in the chain of reactions involved. In the absence of steam, ethyl acetate is formed from ethyl alcohol by catalytic dehydrogenation at 300-350°C.

$$2C_2H_5OH \longrightarrow 2CH_3CHO + 2H_2$$
$$2CH_3CHO \longrightarrow CH_3COOC_2H_5$$

The anhydrous ester in the presence of zinc oxide and chromic oxide at 400°C. is converted into acetone, ethanol, ethylene and carbon dioxide. If steam is admixed with the original reactants, acetic acid tends to result in place of the ester. In the latter instance at temperatures above 400°C. acetone is formed instead of acetic acid. Hydration of ethyl ether to ethanol and the subsequent conversion to acetone in 40 to 50 per cent yield are said to take place when the ether is mixed with 3 to 5 volumes of steam and passed at 400 to 500°C. over a catalyst of mixed oxides of aluminum, iron and magnesium.[14] A 96 per cent yield of acetone from acetaldehyde is stated to be secured from the passage of the aldehyde over an iron oxide-manganese oxide mixture at 400°C.[15] The chain of processes by which ethanol, diethyl ether, acetaldehyde and ethyl acetate are converted into acetone by catalytic decomposition in the presence of steam is represented by Kagan and his collaborators as follows:

[12] J. W. Woolcock, U. S. P. 2,015,094, Sept. 24, 1935, to Imperial Chemical Industries, Ltd.; *Chem. Abs.*, 1935, **29**, 7346.

[13] M. Ya. Kagan, I. A. Sobolev and G. D. Lyubarskii, *Ber.*, 1935, **68**, 1140; *Brit. Chem. Abs.* **A**, 1935, 963; *Chem. Abs.*, 1935, **29**, 6207.

[14] M. Ya. Kagan, I. M. Rossinskaya and S. M. Cherntzov, *J. Gen. Chem.* (*U.S.S.R.*), 1933, **3**, 337; *Brit. Chem. Abs.* **A**, 1933, 1252; *Chem. Abs.*, 1934, **28**, 2323.

[15] N. D. Zelinskii, M. I. Ushakov, B. M. Mikhailov and Yu. A. Arbuzov, *J. Chem. Ind.* (*Moscow*), 1933, No. 7, 63; *Brit. Chem. Abs.* **B**, 1934, 52; *Chem. Abs.*, 1934, **28**, 1015.

$$\begin{aligned} 2C_2H_5OC_2H_5 + 2H_2O &\longrightarrow 4C_2H_5OH \longrightarrow 4CH_3CHO + 4H_2 \\ 4CH_3CHO &\longrightarrow 2CH_3COOC_2H_5 \xrightarrow{2H_2O} 2CH_3COOH + 2C_2H_5OH \\ 2CH_3COOH &\longrightarrow CH_3COCH_3 + CO_2 + H_2O \end{aligned}$$

The overall effect in the case of ethanol may be expressed by the equation:

$$2C_2H_5OH + H_2O \longrightarrow CH_3COCH_3 + CO_2 + 4H_2$$

A number of contact agents have been suggested for promoting the conversion of ethanol or acetaldehyde into acetone by reaction with steam at temperatures up to 500°C. and at atmospheric pressure. The proposed catalysts include the following:

1. A mass containing porous carbon and oxides of zinc, cadmium, manganese or iron.[16]
2. Tin oxide and an oxide of a rare-earth metal, such as cerium.[17]
3. Oxides of metals which are capable of forming isomorphous[18] carbonates. Thus, the alcohol is led over a mixture of iron oxide and calcium carbonate, both deposited on a carrier of iron.[19]
4. An oxide of iron mixed with either nickel or cobalt oxide.[20]
5. Oxygen compounds of nickel (e.g., nickel acetate) with a carrier of oxidized spongy iron, the nickel content not exceeding 20 per cent of the total mass.[21]
6. A mixture of zinc oxide and calcium silicate.[22]
7. A hard cement, produced by treating oxygen compounds of zinc and calcium with water. Such compounds may be prepared by heating calcium and zinc hydroxides with air at 1500°C.[23]
8. Calcium silicate, borate or phosphate.[24]
9. A composite of iron and manganese oxides together with barium carbonate.[25]
10. A mixed-oxide of zinc and chromium, incorporated with a metal halide.[26]

Kagan[27] reports the production of acetone by passage of a mixture of steam and diethyl ether at 400-500°C. over a mixture of metallic oxides, such as those just mentioned.

Also, the direct conversion of vaporized ethanol into acetone in the absence of steam has been suggested. The partial pressure of the alcohol is maintained at less than 1 atmosphere, and temperatures of the order of 400 to 500°C. are employed. The proposed catalysts include oxides of chromium, manganese, copper and iron[28] and a mixture of zinc oxide with ferric or zinc chloride.[29]

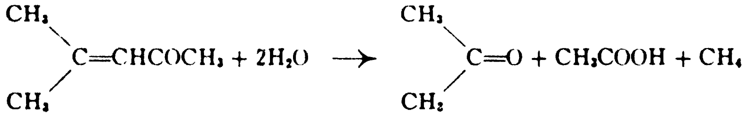
Dreyfus[30] proposes to convert ethanol into acetone by treatment with free oxygen in the vapor phase at temperatures of 350-550°C. A promoter composed of iron oxide and calcium carbonate is employed. Other contact agents include calcium oxide or calcium silicate.[31]

Acetaldehyde vapor at a partial pressure of 25-300 mm. of mercury may be converted into acetone by passage at 400-500°C. over catalysts consisting of zinc, iron, copper and manganese.[32] Esters of aliphatic acids and monohydric alcohols, such as ethyl acetate, are reported to be converted into ketones by treatment at 400-600°C. in the presence of the oxides of iron, manganese or zinc, or the carbonates of calcium, strontium, barium and magnesium.[33]

Also gaseous acetic acid is stated to be converted to acetone by conducting the vapor at 300° to 400°C. over activated carbon admixed with an oxide of calcium or zinc.[34] The mechanism of this reaction when calcium hydroxide is employed has been discussed by Nieuwland.[35] He points out that with the acid in the gaseous phase, the conversion may be described as:

$$\begin{aligned} 2CH_3COOH + Ca(OH)_2 &\longrightarrow (CH_3COO)_2Ca + 2HOH \\ (CH_3COO)_2Ca &\longrightarrow CH_3COCH_3 + CaCO_3 \\ CaCO_3 &\longrightarrow CaO + CO_2 \\ CaO + HOH &\longrightarrow Ca(OH)_2 \end{aligned}$$

Acetone may be prepared by the interaction of acetylene and water as described in Chapter 28. It is interesting to note that mesityl oxide and acetylphthalimide have been recommended for the production of acetone. The activity of various promoters for the hydrolysis of mesityl oxide has been studied.[36] It is stated that the hydrolysis, which may be represented as:



$$(CH_3)_2C{=}CHCOCH_3 + 2H_2O \longrightarrow \begin{matrix} CH_3 \\ CH_2 \end{matrix}{>}C{=}O + CH_3COOH + CH_4$$

may be effected by conducting the vapors of the oxide together with steam, over silica gel. By employing temperatures of 200 to 350°C. at 1 atmosphere pressure, a yield of 19 to 32 per cent of the theoretical amount of acetone is reported. Substitution of aluminum oxide and of thorium oxide for the silica gel is stated to lower the amount of ketone to 8 per cent and 2.3 per cent, respectively.

Acetylphthalimide, $C_6H_5(CO)_2NCOCH_3$, may be subjected to pyrolysis to furnish acetone.[37] Fifty parts of the former substance when heated to 240-325°C. for a period of 2 hours yielded only 1 part of acetone, however.

PROPERTIES AND REACTIONS OF ACETONE

Acetone is a colorless mobile liquid having the following physical constants: b.p. 56.15°C.; m.p. —94.9°C.; d_4^{15} 0.79705; critical temperature 234.4°C.; latent heat of vaporization 125.28 Cal. per kg. at 56.3°C.[38]

In comparing the toxicity of acetone with that of methanol, it has been stated that acetone depresses the heart to a greater extent than does the alcohol, but that recovery is much more complete with the former.[39] With mortality as a criterion, methanol is said to be more toxic. With mixtures of the two, the action of acetone is reported to predominate at high concentrations and that of methanol in low concentrations.

Determination of Acetone. Various methods have been suggested for the qualitative and quantitative determination of acetone. Kolthoff[40] points out that as little as 1 mg. of acetone in a liter of solution can be detected by heating 10 cc. of the solution with 1 g. of solid potassium hydroxide and 10 drops of salicylaldehyde to 70°C. on a water bath. Formation of a red ring on the surface of the solution indicates the presence of acetone. Further, vanillin (*m*-methoxy-*p*-hydroxybenzaldehyde) is said to be as sensitive as salicylaldehyde and to have the added advantage of being a specific reagent for acetone in that it does not react with methyl ethyl or aromatic ketones. A spot test to detect as little as 0.5 mg. of acetone has been advocated.[41] A drop of the solution under analysis is dissolved in ether together with a drop of *o*-nitrobenzaldehyde and the solution evaporated. Chloroform is incorporated in the reaction tube, and if acetone is present, indigotin (indigo blue) is formed.

The quantitative determination of acetone has been accomplished by a number of methods. In one of these the acetone is dissolved in water, and a measured amount of caustic soda and iodine incorporated in the solution. The latter is then acidified with sulphuric acid and the excess iodine titrated with sodium thiosulphate.[42] The method depends upon the oxidation of acetone to sodium acetate and iodoform by caustic soda and iodine. Iodine which has not reacted is estimated after the sodium hydroxide has been neutralized. In a modification of the above procedure, it is suggested that the relative insolubility of iodoform in water[43] be made the basis of determination. In this case the volume of precipitated iodoform is compared with the amount obtained from aqueous acetone solutions of known concentration.[44] Another method of estimating acetone is by reaction with hydroxylamine hydrochloride. The interaction may be represented as,

$$CH_3COCH_3 + H_2NOH \cdot HCl \longrightarrow CH_3CNOHCH_3 + HCl + H_2O$$

---

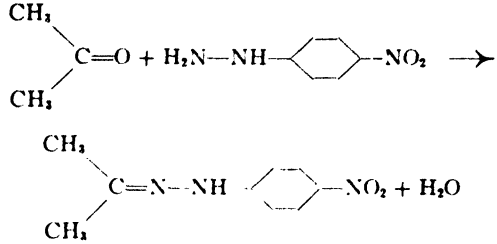
[43] Iodoform is soluble in water to the extent of 0.01 g. per 100 cc. at 25°C.

[44] S. Cornet-Cals and M. R. Cornet-Cals, *Halle aux cuirs*, 1936, 30; *Chem. Abs.*, 1936, 30, 2881.

whereby acetoxime and hydrochloric acid are formed. The amount of acid liberated is then determined by titration with caustic potash.[45] The error which may be introduced by the presence of organic acids is said to be decreased by the use of bromophenol-blue as an indicator. The latter has a yellow color when the *p*H is less than 3.0 and changes to violet in the *p*H range of 3.0 to 3.6. The interaction of acetone with 2,4-dinitrophenylhydrazine to form a precipitate of acetone-2,4-dinitrophenylhydrazone has been advocated for the estimation of the ketone.[46]



Comparison of the weights of dinitrophenylhydrazine employed and of hydrazone obtained forms a basis for estimating the amount of acetone reacting. Also, a quantitative colorimetric estimation of acetone has been reported.[47] The ketone mixture is diluted with water and *o*-nitrobenzaldehyde and caustic soda added. The solution is allowed to stand in the dark for 15 minutes and then compared colorimetrically with known acetone solutions which have been similarly treated.

Decomposition of Acetone. The thermal decomposition of acetone leads primarily to the formation of ketene and methane.

$$CH_3COCH_3 \longrightarrow CH_4 + CH_2{=}CO$$

There is some evidence to show that the breakdown proceeds through a chain mechanism. It has been pointed out that the decomposition may occur by rupture of a molecule of acetone:[48]

$$CH_3COCH_3 \longrightarrow CH_3 + CH_3CO$$

which would be followed by a chain reaction:

$$\begin{aligned} CH_3COCH_3 + CH_3 &\longrightarrow CH_4 + CH_3COCH_2 \\ CH_3COCH_2 &\longrightarrow CH_2{=}CO + CH_3 \end{aligned}$$

In order to ascertain whether the addition of methyl groups brings about a chain reaction in vaporized acetone, the latter was heated with 1 per cent of dimethyl mercury to 350-400°C. Under these conditions the latter decomposed to mercury and methyl radicals. No ketene was produced, indicating that the chain reaction mentioned above had not taken place. Instead, a substance identified as acetonylacetone, $CH_3COCH_2CH_2COCH_3$, was formed in amounts corresponding to the amount of dimethyl mercury incorporated in the reaction zone. It was concluded that the chain reaction given above does not occur below 400°C., but that the acetonyl groups combine among themselves.

$$\begin{aligned} CH_3COCH_3 + CH_3 &\longrightarrow CH_4 + CH_3COCH_2 \\ 2CH_3COCH_2 &\longrightarrow CH_3COCH_2CH_2COCH_3 \end{aligned}$$

Also, Allen[49] advocates picturing the decomposition as a chain mechanism. Velocities of reaction at temperatures in the range 462-529°C. were determined by measuring the change in pressure at definite intervals. The breakdown of acetone to ketene and methane was found to proceed smoothly at 529°C. At lower temperatures (462°C.) it was noted that the measured initial pressure was higher than would be obtained by extrapolation of the pressure-time curve to zero (see Fig. 109). It was concluded that this relatively high pressure represents an induction period. Introduction of glass packing into the reaction vessel (a 1-liter flask) was said to affect the reaction in three ways: (1) the shape of the rate-pressure curve, determined by plotting the logarithm of the pressure against that of the reaction rate constant, was changed from a convex to a concave curve; (2) the apparent rate at high pressures was not affected when the reaction was carried out at 529°C., but decreased to one-half its normal value with the temperature at 465°C.; (3) the induction period was no longer apparent at any temperature. These effects were considered proof of a chain mechanism, for, on the chain hypothesis, a short induction period appears naturally as the time necessary for the chain-carrying radicals to attain a steady concentration. Packing is supposed to shorten the chains, thus rendering the induction period inappreciable and reducing the rate most at lower temperatures, where the chains are longest. Further it was suggested that the change of shape of the rate-pressure curve by packing shows the great complexity of the reaction. The mechanism considered most plausible is:

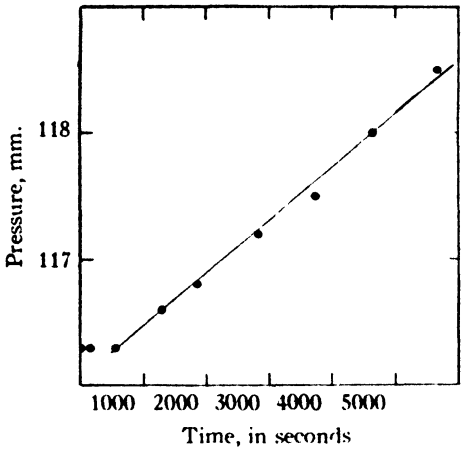

Fig. 109.
Time-Pressure Curve in Thermal Decomposition of Acetone at 462°C. (A. O. Allen)

Courtesy Journal of American Chemical Society

$$\begin{aligned} CH_3COCH_3 &\longrightarrow 2CH_3 + CO \\ CH_3 + CH_3COCH_3 &\longrightarrow CH_4 + CH_2COCH_3 \\ CH_2COCH_3 &\longrightarrow CH_3 + CH_2CO \\ 2CH_3 &\longrightarrow C_2H_6 \\ CH_3 + CH_2COCH_3 &\longrightarrow C_2H_5COCH_3 \end{aligned}$$

It was pointed out that the combination of two acetonyl groups, mentioned before, was not included because the biacetonyl formed would decompose at the temperatures employed.

---

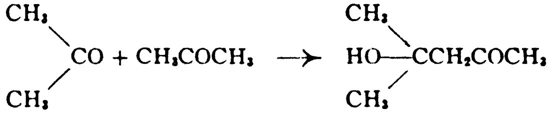
Patat and Sachsse[50] state that although the decomposition of acetone does proceed by free radicals, too few are present to account for the total decomposition. On the other hand, Winkler and Hinshelwood[51] consider that the reaction is homogeneous and that chains must be either absent or very short.

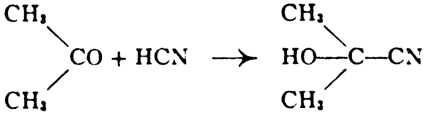
Diacetone Alcohol. When subjected to the action of alkalies, acetone undergoes a condensation similar to the aldol condensation of aldehydes, which results in the formation of diacetone alcohol.



Among the substances aiding in the condensation are sodium, potassium and barium hydroxides, as well as magnesium amalgam.[52] Guinot[53] employs alcohol as a solvent for the alkaline condensing agent. For example, 800 cc. of an alcoholic solution of potassium hydroxide containing 40 g. of the latter was incorporated in 500 g. of ketone at 10°C. The mixture was allowed to stand for 5 hours, neutralized, and distilled to recover diacetone alcohol. It was said that 14 per cent of the acetone was transformed to the alcohol in this manner. For continuous production of diacetone alcohol, acetone may be conducted over solid sodium or potassium hydroxide at 20°C.[54] To separate diacetone alcohol from unchanged acetone, distillation may be carried out at atmospheric pressure after water is added up to 10 per cent of the volume of alcohol present in order to minimize decomposition. When a still temperature of 105-107°C. is reached, practically all of the acetone and some water have been distilled off. The remaining water is removed by vacuum distillation below 105°C. The alcohol may then be distilled off at 166°C. and 760 mm.[55]

Diacetone alcohol has been suggested as a solvent,[56] but it must be employed under neutral or slightly alkaline conditions. In the presence of acids the alcohol tends to decompose to mesityl oxide, which is discussed later in this chapter.

Cyanohydrins. Acetone reacts with hydrogen cyanide to yield an addition product, acetone cyanohydrin.



Scorah and Wilson[57] point out that the addition may be carried out in the liquid phase and at the boiling point of the ketone (56.15°C.). For example, 1 mole of hydrocyanic acid is incorporated in a boiling solution of 1 mole of acetone containing 0.5 per cent of piperidine. After heating is continued for 0.5-1 hour, the products are cooled to 20°C. and acidified with 50 per cent sulphuric acid. Acetone cyanohydrin may then be distilled from the reaction chamber. Addition of quinoline and phosphorus pentoxide is said to bring about a splitting off of a molecule of water from the cyanohydrin, resulting in methacrylonitrile, $CH_2{=}CCNCH_3$. In the preparation of aliphatic cyanohydrins the presence of 0.1 per cent of sodium cyanide is said to accelerate the reaction.[58] One proposed use for acetone cyanohydrin is in the preparation of esters of α-hydroxy fatty acids.[59] For example, 799 g. of the cyanohydrin are heated to 75°C. and 1200 g. of 98 per cent sulphuric acid incorporated. Methanol (100 g.) and hydroquinone (1 g.) are added and the mixture heated on a water bath to 100°C. After 16 hours 300 g. of sodium sulphate are introduced into the reaction flask and the products distilled off. Yields of 545 g. of methyl-α-hydroxy isobutyrate and 218 g. of methyl methacrylate are reported from this procedure.

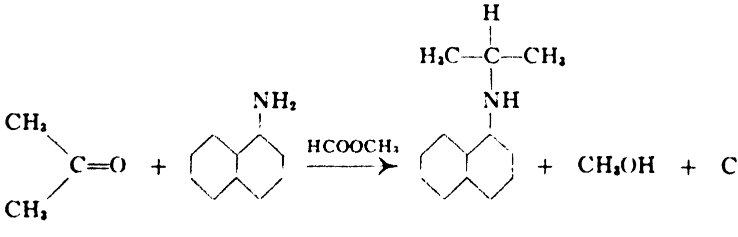
Amines. Acetone reacts with ammonia and with primary and secondary amines to form, respectively, primary, secondary and tertiary amines. For example, acetone may be treated with hydrogen and ammonia at 300°C. and under 200 atmospheres pressure to yield a mixture of isopropylamine and diisopropyl amine, the ratio of the primary to secondary amine being 9:1. An alloy of nickel, sulphur and tungsten is suggested as a contact agent.[60] With a primary amine and acetone in the presence of methyl formate, the production of a secondary amine may be represented as:



It is reported that the above reactants heated to 210°C. for a period of 2 hours give the yield of 90 per cent of the theoretical amount of N-isopropyl-α-naphthylamine.[61] The latter may be further condensed at 240°C. with an aromatic amine to yield a product reported to act as an oxidation inhibitor for rubber.[62] Analogously, acetone interacts with a secondary amine to furnish a tertiary amine. Meuser[63] points out that acetone may be reacted with N-phenyl-β-naphthylamine to furnish N,N-isopropyl phenyl-β-naphthylamine. The reactants are heated in an autoclave to 250°C. with reduced iodides of iron and tin.

drous alkali similar to the ones just mentioned to effect a partial conversion of the ketone to diacetone alcohol.[65] Dilute sulphuric acid is then added in a quantity just sufficient to neutralize the alkali present. The alcohol is admixed with oxalic acid and water at 120°C. to split off the elements of water from the alcohol, producing mesityl oxide in a reported yield of 95 per cent, based on the amount of acetone employed. Unreacted acetone may be distilled from the reaction zone at 56°C. and 760 mm. and recycled (see Fig. 110). The mesityl oxide comes over at 128-130°C. under the same pressure.

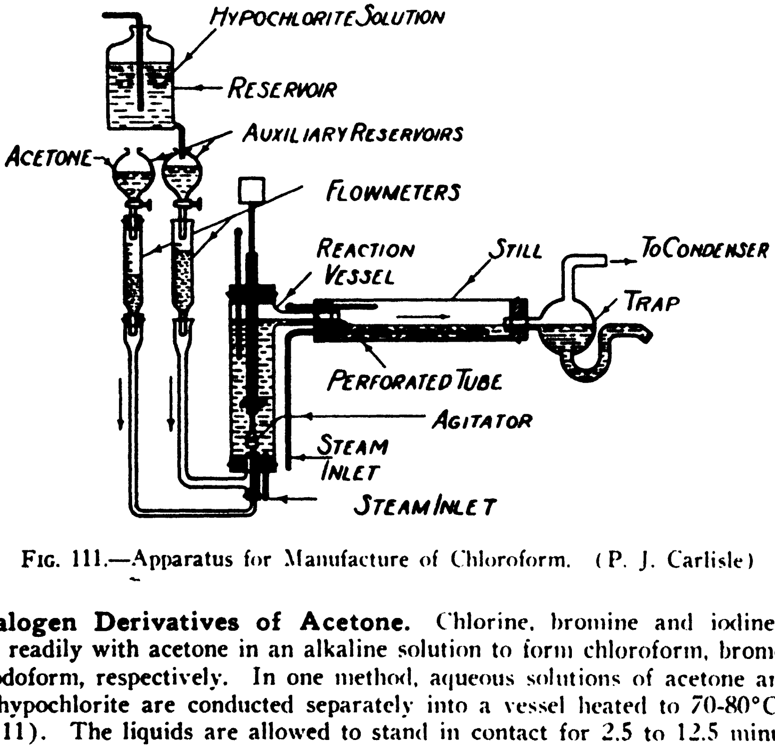

FIG. 111.—Apparatus for Manufacture of Chloroform. (P. J. Carlisle)

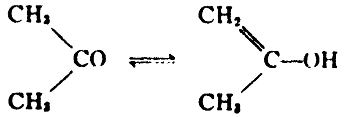
Halogen Derivatives of Acetone. Chlorine, bromine and iodine react rather readily with acetone in an alkaline solution to form chloroform, bromoform, and iodoform, respectively. In one method, aqueous solutions of acetone and calcium hypochlorite are conducted separately into a vessel heated to 70-80°C. (see Fig. 111). The liquids are allowed to stand in contact for 2.5 to 12.5 minutes to give a yield of 84-88 per cent of the theoretical amount of chloroform.[66] A di-substituted ketone, *asym*-dichloroacetone is reported to be secured when the halogenation is effected at the boiling point of the ketone.[67] In one case, 1500 g. of acetone were subjected to the action of chlorine at 56°C. to furnish 1612 g. of *asym*-dichloroacetone. It has been noted that the bromination of acetone is retarded by water, and, to a somewhat lesser extent, by alcohols.[68] As a possible explanation, it was suggested that acetone exists in two tautomeric forms,



$$(CH_3)_2CO \rightleftharpoons CH_2{=}C(OH)CH_3$$

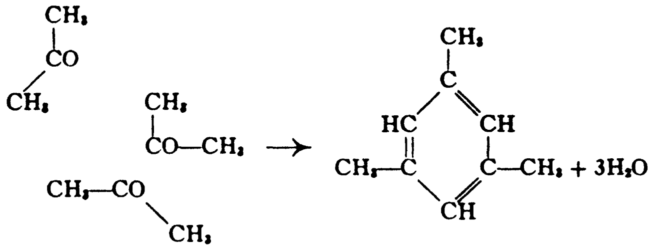
ketonic and enolic, the latter being more reactive with halogens. The retarding effect, therefore, was said to be caused by the formation of a complex addition product of water or alcohol with the ketone form.

Although direct substitution of fluorine in acetone has not been reported, a monosubstituted derivative has been prepared.[69] Bromoacetone is dissolved in ether and heated to 85-95°C. Anhydrous tellurium fluoride is then incorporated in the reaction chamber. The method is said to give 66 per cent of the theoretical yield of fluoroacetone, boiling at 72.5°C.

Miscellaneous Reactions of Acetone. Among the substances which have been obtained from acetone are included mesitylene, isopropyl alcohol, organic acids and peroxides, and keto-alcohols and aldehydes in addition to the compounds previously mentioned.

In the presence of hydrochloric acid, three molecules of acetone unite to form a cyclic compound, mesitylene, 1,3,5-trimethylbenzene.[70] It has been reported that



the amount of mesitylene furnished by this condensation at 175°C. and 100 atmospheres pressure varies with the concentration of the hydrochloric acid.[71] The yield was found to rise rapidly with increasing concentration of hydrochloric acid ($d_4^{20} = 1.19$) until 5 per cent by volume is reached. With proportions of acid between 5 and 50 per cent, a gradual fall in the amount of the cyclic compound occurs, and terpene-like products with a high degree of condensation appear. With a constant concentration of acid at 5 per cent by volume and with varying temperature, the graphical relationship of temperature to yield of mesitylene (based on unrecovered acetone) showed a sharp inflection at 140°C. (see Fig. 112). A similar break was noted at 170°C. when the yield was calculated from the amount of acetone charged into the apparatus. Between 175 and 190°C. the two curves coincided, pointing to a complete utilization of the acetone. At 140°C. 50 per cent of the acetone remains unaffected. At 175-180°C. practically all of the ketone is used up, giving 36 per cent of the cyclic compound.

In another procedure, aluminum oxide is used as a contact agent in place of hydrochloric acid.[72] The oxide, which may be secured by heating a natural alumina hydrate such as bauxite for a period of 1 hour at 600-900°C., is added to acetone, and the two are heated to 330-370°C. under 150-250 atmospheres pressure to give a 40 per cent yield of mesitylene.

The addition of hydrogen to acetone leads to isopropanol. This process is the reverse of the dehydrogenation of isopropanol which was discussed in connection with the preparation of acetone. Acetone and hydrogen may be conducted together over nickel, copper or the oxide or chromite of zinc at temperatures ranging between 40 and 300°C. and at pressures from 1 to 300 atmospheres.[73] In order to suppress any dehydration which may occur with zinc chromite, Lazier[74] proposes to incorporate potassium carbonate in the contact agent. A 10 per cent yield of isopropyl alcohol was obtained as follows. A mixture of 100 cc. of zinc chromite containing 10 per cent of potassium carbonate is placed in a copper reaction tube. Acetone is then pumped at the rate of 1.5 liters per hour through a vaporizing tube heated to 60°C. As the vapors leave the latter they are mixed with compressed hydrogen and conducted over the catalyst bed, which is maintained at 375°C. and a pressure of 200 atmospheres.

Controlled oxidation of acetone results in the formation of carboxylic acids. Flemming and Speer[75] report that acetone and air at 200°C. and under 25 atmospheres in the presence of 0.1 to 1 per cent of manganese and cobalt acetate yield acetic acid. A mixture of trimethylacetic and acetic acid is reported from the interaction of acetone, steam and carbon monoxide at 300°C. and 350 atmospheres pressure.[76] Activated charcoal and aluminum chloride are suggested as promoters for the reaction. Selenious oxide is said to be an effective agent for partially oxidizing acetone to a keto-aldehyde with the formation of but little acid.[77] Hydrogen peroxide, prepared *in situ* by the hydrolysis of persulphuric acid, has been employed to oxidize acetone to acetone peroxide.[78] For example, a 13 per cent solution of persulphuric acid is hydrolyzed by heating to 100°C. for 1 minute. It is then cooled to —20°C. and acetone incorporated slowly. Stirring is continued for 15 minutes at the latter temperature. Acetone peroxide may then be extracted with benzene.

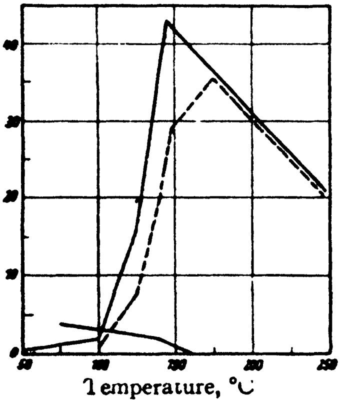

FIG. 112.
Effect of Temperature on Yield of Mesitylene from Acetone. (V. N. Ipatieff, B. N. Dolgov and I. Volnov)

Condensation of acetone with a higher ketone leads to the production of keto-alcohols in a manner analogous to the formation of diacetone alcohol. Thus, acetone and ethyl methyl ketone react at 20°C. in the presence of sodium hydroxide to furnish a mixture of 4-hydroxy-4-methyl-2-hexanone and 5-hydroxy-5-methyl-3-hexanone.[79] The latter compounds are suggested as solvents for pyroxylin.

A number of synthetic resins are prepared by the interaction of acetone, as well as higher ketones, with aldehydes. The condensation products have been proposed for use in molding compositions and as constituents of varnishes.[80]

USES OF ACETONE

Since acetone is one of the best known solvents and because of its ready miscibility with water, alcohol, ether and many esters, mineral and vegetable oils, it finds wide use where solvents are required. Among its miscellaneous applications are the preparation of smokeless powder, storing of acetylene, as a fuel and as a selective solvent for dewaxing lubricating oils.[81]

Acetone has been recommended as a constituent of paint and varnish removers. One such remover contains 20-40 per cent of a petroleum distillate boiling below 115°C., 25-40 per cent of a mixture of methanol, ethanol and acetone, and 20 per cent of ethyl acetate.[82] A composite of 40-60 per cent of a hydrogenated petroleum fraction, 15-40 per cent of acetone and 1-8 per cent of paraffin or ceresin wax has been described as effective for the same purpose.[83] Also, hydrogenated gasoline may be mixed in a volume ratio of 3:7 with isopropanol and acetone. Paraffin wax and cadmium oleate are then incorporated in this solvent to form a liquid effective in removing varnish and lacquer.[84]

In dewaxing lubricating oils, acetone may be employed either alone[85] or mixed with benzol,[86] tetrahydronaphthalene,[87] water-insoluble aliphatic alcohols,[88] higher ketones such as methyl isobutyl or methyl ethyl ketone,[89] *o*-dichlorobenzene,[90] monochlorobenzene,[91] ethylene dichloride,[92] isopropyl ether,[93] bis(2-chloroethyl) ether[94] or a kerosene extract boiling below 300°C.[95] The solvent is added to the oil and the mixture cooled to a point, usually between —10 to —23°C., where the solvent has complete action upon the oil and practically none upon the wax. The precipitated wax is then removed by filtration or centrifuging.

Also, sulphur may be separated from hydrocarbons by the action of acetone with aluminum or zinc chlorides[96] or caustic soda, or potash.[97] It has been reported that acetone, combined with ammonia, is effective in removing unsaturated constituents from mineral oils.[98] A lubricant said to be free flowing when kept under pressure and away from air, but which assumes a heavy consistency when exposed to the atmosphere, may be secured by admixing an extreme pressure lubricant with acetone, carbon dioxide and rubber cement.[99] The lubricant is recommended for use in chassis bearings. Further, acetone is suggested as a solvent for cellulose acetate,[100] asphalt,[101] and tar.[102] Among the miscellaneous uses for which acetone has been employed are included cleansing agents,[103] a solvent for wood preservers,[104] and as a pickling solution for steel when mixed with sulphuric acid.[105] It is interesting to note that a substituted derivative of acetone, dihydroxyacetone, is reported to be a good antidote for hydrocyanic (prussic) acid poisoning.[106]

KETENE

It has been previously mentioned that the thermal decomposition of acetone leads to the formation of methane and ketene.

$$CH_3COCH_3 \longrightarrow CH_4 + CH_2{=}CO$$

Besides the theoretical aspect of the above decomposition, practical production of ketene has also received some attention. For example, ketene may be obtained by conducting acetone vapors through a reaction chamber composed of chromium

and iron which is heated to 550°C.[107] The gases issuing from the heating zone are immediately led to a second chamber (made of copper) which is heated to temperatures of 600 to 750°C. (see Fig. 113). In both steps the pressure is held at 5 lbs. per sq. in. Another proposal is to pass acetone vapors directly into a copper tube heated to 700-850°C., the contact time of the vapors being less than 1 second.[107a]

Because of its instability, it has been proposed that ketene be dissolved, as quickly as it is formed, in an inert solvent, when the unsaturated ketone is to be employed in further synthesis. Thus, the gases secured by thermal decomposition of acetone are scrubbed at 35-55°C. (Fig. 114) with acetone and then conducted into another portion of acetone at 0°C.[108] At the lower temperature a solution of ketene in acetone is formed which may then be utilized in various acetylation reactions. Other solvent liquids mentioned are pentane, hexane, benzene, diethyl ether and methyl ethyl ketone. If the ketene is to be used directly the liquid with which it is to react may be substituted for the solvent liquid. Thus, the gaseous decomposition products are introduced directly into acetic acid to form acetic anhydride or into 2-ethoxyethanol to form 2-ethoxyethyl acetate.[109] Wiezevich and Frolich[110] suggest the production of ketene by passing acetone through a column of molten lead contained in a reaction vessel lined with fireclay. The lead is maintained at the required temperature (600-900°C.) by circulation of a portion of it through a heating coil.

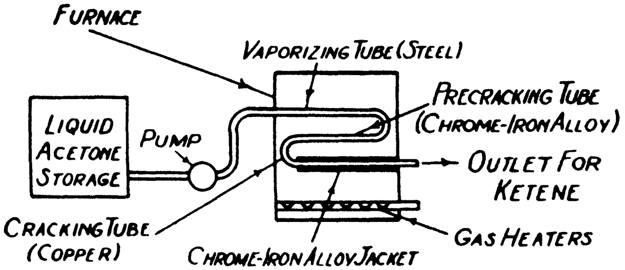

FIG. 113.—Sketch of Method for Thermal Decomposition of Acetone to Ketene. (G. H. Reid)

One method for the laboratory preparation of ketene is as follows.[111] Acetone is dropped directly from a separatory funnel into a quartz reaction tube heated to 650-750°C. The exit gases are led into a Pyrex tube immersed in solid carbon dioxide in order to condense ketene and undecomposed acetone. At the end of a reaction period of 0.5 hour the ketene is distilled off by warming the solution rapidly to the boiling point of acetone (56°C.). The receiver for the distillate is maintained at —80°C. For larger-scale production with the same type of reaction tube, temperatures greater than 750°C. may be employed and unreacted acetone may be recycled through the furnace.[111a] (See Fig. 115.) It is stated that the best yield results when less than 10 per cent of the acetone is decomposed per passage.

Also, ketene may be produced from acetic acid or acetic anhydride by thermal treatment.

$$2CH_3COOH \longrightarrow (CH_3CO)_2O + H_2O \longrightarrow 2CH_2{=}CO + H_2O$$

Thus, acetic acid may be heated to 740°C. at 35 mm. pressure in the presence of sodium phosphate, which promotes the formation of the anhydride.[112] In the thermal treatment of acetic anhydride to give ketene, Wiezevich[113] suggested heating the anhydride to 800-1000°C. for 5 seconds by passing through a heated copper vessel and then suddenly cooling the product. Also, there is introduced into the reacted stream an organic liquid insoluble in water and inert to ketene to facilitate the subsequent settling out of water. Recovery of the ketene, unused acid anhydride and added organic liquid is then made. The latter may be chlorobenzene, butyric acid, *sec*-amyl acetate, phenetol or isopropyl ether.

Properties and Uses of Ketene. Ketene is a gas at ordinary temperatures; it can be condensed to a liquid boiling at —56°C. and solidifying at —151°C.[114] The substance tends to polymerize to resinous matter at ordinary temperatures, although the pure liquid is stable at —80°C. Polymerization may be inhibited to a considerable extent by various solvents.[115]

The photochemical decomposition of ketene has been studied to determine the mechanism which it follows.[116] One apparatus consisted of a cylindrical quartz cell of 20 cc. capacity immersed in a constant-temperature water bath with a window of crystal quartz. Illumination was secured with a quartz mercury vapor lamp. It was found that the decomposition of ketene is accompanied by a pressure increase and that the gaseous products are carbon monoxide and ethylene. In addition a solid film was deposited gradually on the walls during illumination. When only ketene was present in the illuminated zone the reaction yielded quantitatively carbon monoxide and ethylene in the theoretical ratio. Also, it was noted that the reaction, as measured by the increase in pressure, stops before all the ketene has been consumed. Since the same result occurred when ethylene was added, it was concluded that the retardation of the decomposition was due to the presence of the latter. The solid deposit was assumed to have the composition $(CH_2)_n$, since all of the original ketene was accounted for either as free carbon monoxide or as undecomposed ketene, and because no hydrogen or deposits of free carbon were observed among the products. From these data it was deduced that the primary reaction upon absorption of light is:

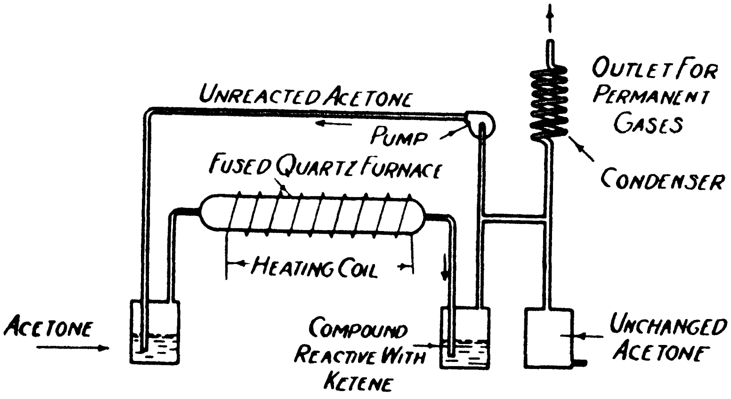

Fig. 115.—Method of Preparation of Ketene, Employing Recycling Operation. (F. O. Rice)

$$H_2C{=}CO \longrightarrow H_2C + CO$$

---

[114] Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[115] Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935.

[116] W. F. Ross and G. B. Kistiakowsky, *J.A.C.S.*, 1934, 56, 1112; *Chem. Abs.*, 1934, 28, 4314; *Brit. Chem. Abs.* A, 1934, 740.

Further, from the information obtained that the quantum yield with the 3130Å. line was near unity, the conclusion was made that the reaction:

$$H_2C{=}CO + CH_2{=} \longrightarrow CO + C_2H_4$$

does not occur to any significant extent, so that methylene radicals must react with each other to form ethylene. The retardation and finally complete discontinuance of pressure increase was thought to be attributable to the reaction of methylene groups with ethylene, the ultimate product being the solid polymer. On the other hand, Norrish, Crone and Saltmarsh[117] maintain that the reaction between a methylene group and ketene does take place rather than the combination of methylene groups.

Acetylation with Ketene. The addition of ketene to alcohols results in acetylation of the latter.

$$ROH + CH_2{=}CO \longrightarrow ROOCCH_3$$

where *R* is an alkyl, cycloalkyl or aryl group. Ketene is a powerful acetylating agent, and, under proper conditions, will add to most organic substances containing active hydrogen atoms, provided that the compounds can be liquefied or dissolved in a solvent inactive toward ketene.[118] In the procedure, 10 g. of the substance to be acetylated were placed in a reaction flask, fitted with inlet and outlet tubes. The inlet tube was connected with a reservoir containing ketene at —80°C. By allowing this reservoir to warm up, ketene could be passed through the reaction tube at a convenient rate. The outlet from the latter was connected to a third tube, kept at —80°C., in which the unreacted ketene was condensed. The reaction vessel was heated in an oil bath above the melting point of the compound to be acetylated. In this manner cetyl alcohol was converted at 180°C. into cetyl acetate, *ter*-butyl alcohol at 80°C. into *ter*-butyl acetate, and phenol at 183°C. into phenyl acetate. It is interesting to note that attempts to acetylate benzamide by means of ketene at 180°C. resulted in the production of benzonitrile and acetic anhydride. The probable course of this reaction was said to be:

$$\begin{aligned} CH_2{=}CO + C_6H_5CONH_2 &\longrightarrow C_6H_5CONHCOCH_3 \\ C_6H_5CONHCOCH_3 &\longrightarrow C_6H_5CN + CH_3COOH \\ CH_3COOH + CH_2{=}CO &\longrightarrow (CH_3CO)_2O \end{aligned}$$

For the production of phenyl acetate from ketene and phenol 0.5 to 2 per cent of sulphuric acid may be employed as a promoter to give a reported yield of 92-93 per cent of the theoretical amount of phenyl acetate, using a contact period of 1.5 hours.[119]

Hurd and Williams[120] have studied the interaction of ketene with thioalcohols, aromatic aldehydes, hydroxy acids and salicylic acid. With ethanethiol, the acetylation may be represented as:

$$CH_2{=}CO + C_2H_5SH \longrightarrow CH_3COSC_2H_5$$

To effect this transformation, 4 g. of liquid ketene and 3.5 g. of ethanethiol were mixed and kept at —80°C. for 3 days and then warmed to 20°C. On distillation,

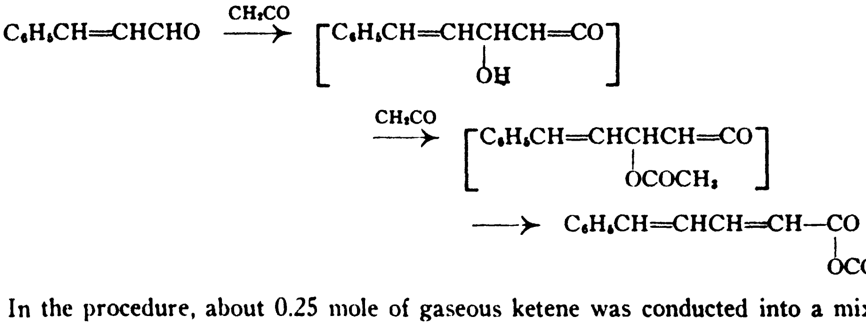
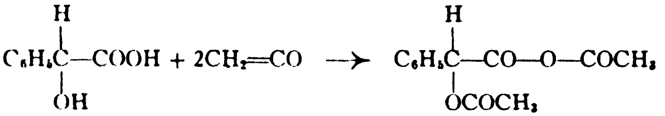
[120] C. D. Hurd and J. W. Williams, *J.A.C.S.*, 1936, **58**, 962; *Chem. Abs.*, 1936, **30**, 5182.

5.1 g. of ethylthioacetate were collected between 109 and 115°C. Cinnamic aldehyde unites with ketene in the presence of fused potassium acetate to form an anhydride of β-styrylacrylic acid.



$$C_6H_5CH{=}CHCHO \xrightarrow{CH_2CO} \left[C_6H_5CH{=}CH\underset{\overset{|}{OH}}{C}HCH{=}CO\right] \xrightarrow{CH_2CO} \left[C_6H_5CH{=}CH\underset{\overset{|}{OCOCH_3}}{C}HCH{=}CO\right] \longrightarrow C_6H_5CH{=}CHCH{=}CH{-}\underset{\overset{|}{OCOCH_3}}{CO}$$

In the procedure, about 0.25 mole of gaseous ketene was conducted into a mixture of 2 g. of fused potassium acetate and 10 g. of cinnamic aldehyde. The products were dissolved in ether and extracted with a 10 per cent caustic soda solution. When sulphuric acid was added to the alkaline extract β-styrylacrylic acid crystallized out. The addition of ketene to mandelic acid results in the formation of an acid anhydride.



$$C_6H_5\underset{\overset{|}{OH}}{\overset{\underset{|}{H}}{C}}{-}COOH + 2CH_2{=}CO \longrightarrow C_6H_5\underset{\overset{|}{OCOCH_3}}{\overset{\underset{|}{H}}{C}}{-}CO{-}O{-}COCH_3$$

To illustrate this, 0.08 mole of ketene gas is passed into a solution of 5 g. (0.033 mole) of mandelic acid in acetone. The acetone is then removed by distillation under reduced pressure, leaving acetylmandelic acetic anhydride, a viscous, light red liquid. Acetylsalicylic acetic anhydride may be secured in a similar manner from salicylic acid (*o*-hydroxybenzoic acid) and ketene. Addition of water to the anhydride furnishes acetylsalicylic acid.

Also, it has been reported that acetylation may proceed through a Friedel-Crafts reaction.[121] Ketene was passed into a suspension of 120 g. of aluminum chloride in 100 cc. of benzene, maintained at 0°C. Stirring was continued until evolution of hydrogen chloride ceased. The product was poured on ice and extracted with benzene and the extract washed with water, dried and distilled. Two cuts were retained: one, boiling at 90°C. under 15 mm. pressure, contained 15 g. of acetophenone ($C_6H_5COCH_3$); the second, which boiled at 110°C. under 15 mm. pressure, consisted of 7 g. of *p*-ethylacetophenone. It was thought probable that the formation of the latter compound was due to the presence of ethylene in the ketene. Acetyl chloride, also an acetylating agent, may be prepared by passing ketene and hydrogen chloride at about 100°C. over active carbon or silica gel.[122]

One of the suggested uses for the acetylating property of ketene is in the preparation of an accelerator for vulcanizing rubber.[123] Ketene is prepared by conducting acetone vapors through a silicon dioxide tube heated to 600-700°C. and equipped with a copper spiral. The gases issuing from the tube are led through a condenser to remove unchanged acetone. The ketene is then passed into a solution of mercaptobenzothiazole, $C_6H_4(NSC{\cdot}SH)$, in chloroform. The acetylated thiazole is a deactivated compound which may be reactivated by heating just before it is to be used in the vulcanization step.

The reaction of ketene with haloamines has been investigated.[124] Among the latter substances were monochloroamine, dibromoamine, nitrogen trichloride and dimethylchloramine. In the procedure ether solutions of the amine and ketene were cooled to —60°C. and admixed. At the end of 3 hours, the reactants were warmed to room temperature (20°C.) and the precipitate which formed was filtered. Some of the results obtained are indicated in Table 101.

TABLE 101.—*Reaction of Ketene with Haloamines.*

Polymerization of Ketene. Rice and Greenberg[125] report that ketene does not polymerize to an appreciable extent in the gas phase. When introduced into a Pyrex vessel over mercury the gas showed no decrease in volume over a period of an hour. Brown spots of polymerized ketene then began to appear on the surface of the glass, but the formation of these was erratic. However, liquid

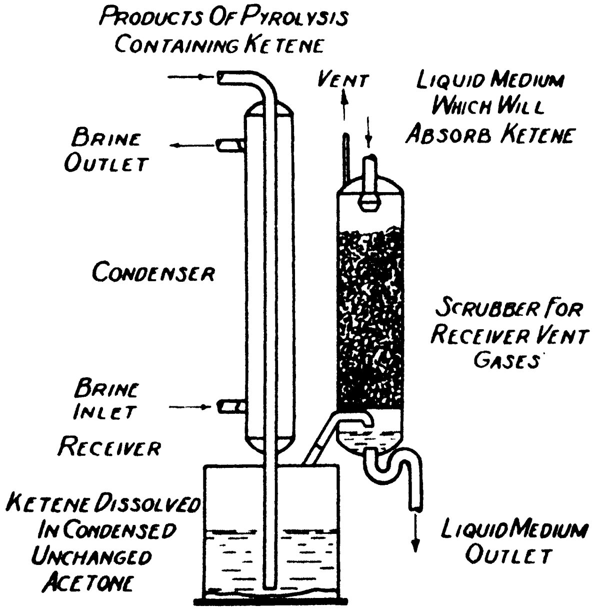

FIG. 116.—Sketch of Apparatus for Preparation of Diketene. (G. H. Law)

ketene was reported to polymerize completely in 1.5 hours, when it was allowed to warm up from —80°C. to 0°C. The rate of polymerization was stated to follow a bimolecular law.[126] Further, it was pointed out that the polymerization is entirely independent of the presence or absence of oxygen, peroxides, hydroquinone and anthraquinone.

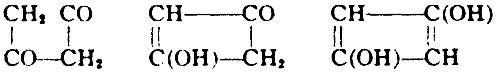
Controlled polymerization of ketene to cyclobutane-1,3-dione, b.p. 127°C., has been carried out with the aid of such metals as steel, copper or chrome nickel steel.[127] For example, ketene is first separated from its acetone solution by cooling to solidify the acetone. Ketene is then liquefied by liquid air, placed in a steel bomb, and allowed to warm up to 25°C. under its own pressure. Cyclobutane-1,3-dione is said to be furnished in amounts up to 85 per cent of theoretical. Also, it has been suggested that the ketene-containing gases from the pyrolysis of acetone be utilized to prepare diketene directly.[128] Such gases may contain, by volume, about 8 per cent of ketene, 10 per cent of methane, 3 per cent of ethylene and carbon monoxide and about 79 per cent of unchanged acetone. The latter is removed by conducting the gases through a brine-cooled condenser (see Fig. 116). The ketene dissolves in the liquid acetone, forming a 10 per cent solution which leaves the condenser at —10°C. and is collected in an uncooled receiver. As the temperature in the receiver rises, the ketene polymerizes slowly to diketene. Uncondensed gases are led to a tower where they are scrubbed with acetone to recover any uncondensed ketene.

Constitution of Diketene. The structure of diketene may be represented as a diketone, keto-enol or dienol.



Measurements of the dipole moment, molecular refractivity and heat of formation have been employed to establish the constitution of this dimer.[129] The dipole moment[130] of dimeric ketene was estimated to be 3.15 at 25°C. in benzene solution and 3.30 in carbon tetrachloride. Calculated values of the dipole moment for the diketone form is zero, for the keto-enol form, 3.0-3.2, and for the dienolic form, 0-3.3. On this basis the keto-enol form was stated to be most probable. Also, measurement of the molecular refractivity[131] substantiated the keto-enol form. In this case the refractivity of dimeric ketene was found to be 20.14, while that calculated for the diketone was 18.99, for the keto-enol, 20.16, and for the dienol, 21.32. The observed heat of formation of diketene (1081 Cal. per mole) was found to be compatible with those calculated for the diketone form (1101 Cal. per mole) and the keto-enol form (1075 Cal. per mole). The calculated value for the

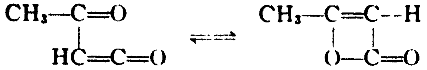
[130] Dipole moment is the product of the magnitude of the equal and opposite ionic charges and of the distance by which they are separated.

[131] Molecular refractivity may be expressed as

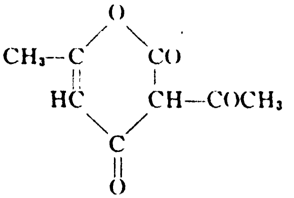
$$[R] = \frac{(n-1)}{d} M$$

where n is the index of refraction, d the density, and M is the molecular weight.

dienol form is somewhat lower (1049 Cal. per mole). On the other hand, Hurd and Williams[132] maintain that the structure of the dimer[133] of ketene may be represented as acetylketene or a resonance isomer[134] of this substance:



The calculated heat of formation of acetylketene was found to be 1086 Cal. per mole, which is in fairly close agreement with the value listed above. Furthermore, according to Hurd and Williams, the structure proposed by them would account for the further polymerization to the tetramer, which is dehydroacetic acid.



One suggested use for diketene is in the preparation of acetoacetanilide.[135] As an illustration, diketene is slowly added to a solution of aniline in toluene, maintained at 50 to 70°C. On cooling the reaction mixture to 20°C. a yield of the crystals separates, and on further cooling to 5°C. another crop of acetoacetanilide is secured. Subsequent evaporation of the mother liquor yields additional crystals of both acetanilide and acetoacetanilide from which the latter may be extracted with caustic soda solution.

Preparation of Higher Ketones

The acetone homologues are good solvents for many purposes. In the cellulose lacquer industry especially their higher boiling points make these ketones in some respects superior to acetone.[136] They have been prepared by the distillation of wood, the dry distillation of the calcium salts of the aliphatic acids, the oxidation of alcohols, the condensation of organic acid chlorides with hydrocarbons and the reaction of lower aliphatic ketones with aliphatic primary alcohols.

Preparation from Secondary Alcohols. *Methyl ethyl ketone*, $CH_3COCH_2CH_3$, is a colorless liquid of pleasant odor, boiling at 78.6°C. One method of preparation is by the oxidation of secondary butyl alcohol. Batalin and Sekretareva[137] reported an 88 per cent yield of the ketone by oxidizing *sec*-butanol at about 500°C. with the aid of a zinc oxide catalyst. The main fraction of the condensate, boiling from 78 to 81°C., had d_4^{20} 0.8057, $n_D^{15.9}$ 1.382. For producing a higher aliphatic ketone from a lower one a mixture of the latter with a lower aliphatic primary alcohol together with hydrogen or nitrogen may be led over a catalyst at 150 to 400°C. The contact agent suggested is alumina containing small proportions of copper, silver, cupric or cuprous oxide, silver oxide or molybdenum trioxide. In this manner acetone and methanol give methyl ethyl ketone, and methyl propyl ketone is prepared from ethanol and acetone.[138] Likewise, methyl amyl ketone results from butyl alcohol and acetone and higher ketones from ethanol and methyl ethyl ketone.

A commercial plant for the separation of methyl ethyl ketone from methyl propyl ketone has been described by I. F. Chistov and A. M. Terekhov, *Lesokhimicheskaya Prom.*, 1934, 3, No. 11, 15; *Brit. Chem. Abs.* B, 1935, 1036; *Chem. Abs.*, 1935, 29, 2911. The density, vapor pressure and index of refraction of methyl ethyl ketone as functions of temperature are discussed by W. A. Felsing, L. Shofner and N. B. Garlock, *J.A.C.S.*, 1934, 56, 2252; *Chem. Abs.*, 1935, 29, 670; *Brit. Chem. Abs.* A, 1935, 22.

Methyl propyl ketone, $CH_3COC_3H_7$, may also be secured by the catalytic dehydrogenation of *sec.*-pentanol.[139] The alcohol is heated to 400°C. in contact with an alloy of 60 per cent copper, 38.5 per cent zinc and 1.5 per cent tin.[140] Other ketones result on similar treatment of different secondary alcohols. Methyl propyl ketone is said to result from the treatment of a mixture of acetone and ethanol at 150-400°C. with a mixed catalyst, e.g., magnesium, 89; aluminum, 8; copper, 2; and silver, 1 per cent.[140a] Higher ketones may also be prepared by condensing ketones with aldehydes and subjecting the product to further treatment.[141] With an alkaline catalyst, ethylhexaldehyde and acetone yield undecyl ketol, which, on losing water, forms an unsaturated undecylene ketone, $C_4H_9CH(C_2H_5)CH=CHCOCH$, boiling at 229°C. Hydrogenation gives a saturated ketone boiling at 93°C.

Di-*n*-propyl ketone, $C_4H_9COC_4H_9$, which boils at 143.5°C., is a solvent for both cellulose nitrate and acetate and also for rubber, natural and synthetic resins, and for linseed and castor oils. In addition, it is free from toxicity and has a pleasant sweetish odor.[142] To convert *n*-butanol to dipropyl ketone, the alcohol may be subjected at 400 to 500°C. to the action ot oxygen compounds of such metals as iron, copper and manganese mixed with oxides of zinc, magnesium or calcium. Subatmospheric pressures are recommended.[143] Dipropyl ketone may be produced indirectly from the fermentation of carbohydrates.[144] The latter, when inoculated with a lactic ferment, will produce lactic acid, (α-hydroxypropionic acid). The fermentation is effected in the presence of calcium carbonate to form calcium lactate. The liquid is then inoculated with a butyric ferment to convert the lactate to calcium butyrate. The latter, after recovery in a concentrated form, is treated with sulphuric acid to liberate butyric acid, which may be collected by distillation. Passage of the fatty acid at 350°C. over thorium oxide deposited on pumice causes conversion to dipropyl ketone.

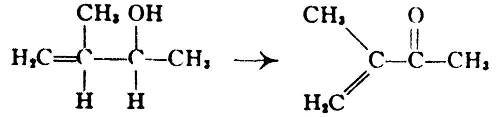
OTHER KETONES FROM ALCOHOLS

Dehydrogenation of menthol by conducting a mixture of its vapor with steam over catalysts at 185°C. is said to give a 96 per cent yield of methone.[145] Also, borneol may be converted into camphor by dehydrogenation in the liquid phase.[146] For example, the alcohol is mixed with benzene in the ratio 3:1 by weight and the two placed in a closed vessel with a small proportion of nickel. The reaction chamber is then heated to 200°C. under a pressure of 100 lbs. per sq. in. Oxidation of a secondary alicyclic alcohol, such as cyclohexanol, to the corresponding ketone is said to be possible by passage of the former in vapor phase, with oxygen, over a catalyst of metallic silver at temperatures between 500 and 600°C.[147]

Unsaturated Ketones from Alcohols. Dehydrogenation or oxidation of unsaturated alcohols with the aid of catalysts leads to the production of unsaturated ketones. Groll[148] converted 2-methyl-1-butene-3-ol into methyl isopropenyl ketone by passing the alcohol over brass spelter in a copper tube heated above 250°C.



Similar treatment of 2-methyl-2-butene-4-ol gave β,β-dimethylacrolein. Silica gel and active alumina when used as catalysts in this treatment are reported to give saturated ketones in place of the unsaturated.[149] Thus, phenylisopropenylcarbinol, $C_6H_5CH(OH)C(CH_3)=CH_2$, passed over active alumina, would give phenyl isopropyl ketone. On the other hand, the same unsaturated alcohol is said to give the corresponding unsaturated ketone by oxidation at about 410°C. in the presence of vanadyl sulphate supported on silica gel.[150]

KETONES FROM PARAFFINS AND CYCLOPARAFFINS

An interesting observation in the field of organic synthesis is that the Friedel-Crafts reaction is in many cases applicable to olefins, paraffins and cycloparaffins. Thus, with the aid of condensing agents, organic acid chlorides will react with these types of hydrocarbons to yield ketones.

By the condensation of *n*-pentane with acetyl chloride in the presence of aluminum chloride, Hopff[151] obtained a ketone which he considered to be 2-acetylpentane (methyl *n*-propyl acetone), $CH_3COCH(CH_3)CH_2CH_2CH_3$. However, Nenitzescu and Chicos[152] report that the main product is methylisopropylacetone (3,4-dimethylpentan-2-one) accompanied by some methylisopropenylacetone (3,4-

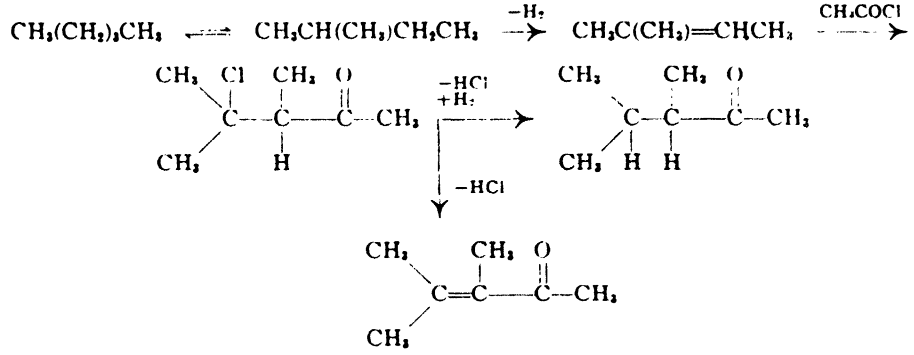
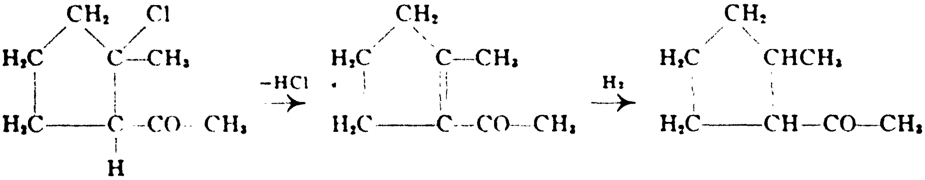
dimethyl-3-penten-2-one). To explain this reaction, initial isomerization of *n*-pentane to 3-methylbutane was postulated. The following scheme was proposed:



In a similar manner *n*-hexane and acetyl chloride gave 4-methyl-3-ethyl pentan-2-one and 4-methyl-3-ethyl-3-penten-2-one.

A somewhat analogous behavior has been found in the action of aluminum chloride and acetyl chloride on cyclohexane.[153] The reported mechanism is that methylcyclopentane is first formed, which loses hydrogen to yield a methylcyclopentene. The latter adds acetyl chloride to give a chloroketone, which in the presence of inactive aluminum chloride splits out hydrogen chloride, forming 1-methyl-2-acetylcyclopentene. With active aluminum chloride, however, hydrogenation also takes place to 1-methyl-2-acetylcyclopentane.



In an investigation of the constituents of commercial petroleum benzine, treatment with aluminum chloride and acetyl chloride gave large yields of cyclic ketones, indicating the presence of considerable amounts of alkylcyclopentanes in the fractions.[154] Cyclohexane hydrocarbons were converted to benzenoid hydrocarbons by dehydrogenation, and aromatic hydrocarbons were removed by oleum treatment before the fractions were subjected to the aluminum chloride-acetyl chloride reaction. In each case unsaturated ketones were first obtained (20 to 60 per cent yields) which could be reduced to saturated ketones. Further hydrogenation gave cycloparaffins.

According to Schaarschmidt[155] saturated paraffin and cycloparaffin hydrocarbons may be converted to corresponding ketones by treatment with phosgene and aluminum halides at temperatures of +5 to —15°C. Thus, isopentane will yield diisoamyl ketone in the presence of aluminum chloride. If *n*-pentane is also present in the original reaction mixture, it may be separated and treated with phosgene and either the bromide or iodide of aluminum. It has also been proposed to employ carbon monoxide in place of phosgene.[156] Thus, isopentane or methylcyclohexane may be treated with carbon monoxide and aluminum bromide at 0 to 20°C. under pressure. The resulting intermediate complex is decomposed with cold water or ice to yield ketones.

The reaction of selenious acid or anhydride with cyclic compounds containing the group $CH=CHCH_2$ is said to give unsaturated ketones.[157] A solvent, e.g., benzene, may be employed for the selenium compound and the reaction carried out under pressure. Methylcyclohexene, 1-menthene, 3-menthene, α-pinene, β-pinene, dipentene and eugenol may be treated in this manner.

Higher Ketones from Carboxylic Acids

It is reported that simple olefin hydrocarbons may be converted into aliphatic carboxylic acids by direct combination with carbon monoxide and steam under high pressure according to the reaction,

$$RR'C{=}CR''R''' + H_2O + CO \longrightarrow CHRR'\cdot CR''R'''COOH$$

where R, R', R'' and R''' represent hydrogen atoms or alkyl radicals.[158] The reaction is said to be catalyzed by volatile halides, such as hydrogen chloride,[159] by active carbon and ammonium chloride,[160] and by boron phosphate.[161] Thus, propionic acid may be obtained from ethylene by the above reaction at 350°C. and 700 atmospheres. Carboxylic acids of this type may be treated catalytically to give ketones, so that the two types of reaction in conjunction form an indirect method of making ketones from olefins. Practically theoretical yields of diethyl ketone have been reported[162] from treatment of propionic acid vapor at 300-370°C. in the presence of a thoria aerogel catalyst.[163] In the procedure, the acid was distilled into a catalyst chamber consisting of two concentric glass tubes sealed at the ends so that a 4 mm. space was formed between them (see Fig. 117). The lower 5 cm. of the annular space was filled with broken pumice, and above that was placed 18 g. of the catalyst. The balance of the space was filled with pumice to aid in bringing the entering gases to the required temperature before reaching the aerogel. Heaters were placed inside as well as outside of the catalyst chamber to obtain a maximum heating surface. The yields of diethyl ketone varied from 94.5 to 100 per cent, depending on the temperature (300 to 374°C.) and rate of flow of vapor (3.0 to 12.3 g. per minute). In a similar manner, 94.4 to 100 per cent yields of di-*n*-butyl ketone and 92.8 to 100 per cent yields of di-*n*-heptyl ketone were obtained from *n*-valeric acid and from caprylic acid, respectively. Other catalysts for the decomposition of acids to ketones include oxides of thorium and cerium.[164]

Also, oleic acid is said to be converted into oleone, a waxy ketone, in 83 per cent yield by contact with reduced iron or ferric oxide at 200-320°C. in the presence of a non-oxidizing gas such as carbon dioxide.[165] A proposed method for the preparation of aldehydes and ketones from petroleum acids consists in converting the latter into α-bromo acids and thence into α-hydroxy acids which are subjected to dry distillation.[166]

Condensation of aromatic hydrocarbons with acyl chlorides by action of Friedel-Craft's condensing agents furnishes aralkyl ketones. In the case of monoalkyl benzenes the acyl group is said to be substituted in the para position.[167] The following example illustrates the preparation of *p*-*n*-propylpropiophenone. A mixture of 204 g. of *n*-propylbenzene and 150 g. of propionyl chloride was slowly added to a stirred suspension of 150 g. of aluminum chloride incorporated in 200 cc. of carbon disulphide. After the evolution of hydrogen chloride ceased, 30 g. of aluminum chloride were added and stirring continued. In the synthesis of methyl naphthyl ketones from naphthalene and acetyl chloride, Rivkin[168] found that less resinous by-products were formed if the aluminum chloride was added slowly to the mixture of reactants in a solvent. The condensations were effected in a closed copper container provided with a mechanical stirrer. Optimum yields were obtained when concentrated solutions were employed and the temperature maintained around 10°C. In one case, 130 g. of naphthalene and 80 g. of acetyl chloride were dissolved in 1000 g. of benzene. To 300 g. of this solution were added 150 g. of aluminum chloride, and after a few minutes of stirring, the remaining portions of the reactants were introduced dropwise, the temperature being kept between 10 and 13°C. At the end of 6 hours a complex compound separated from the solu-

FIG. 117.—Apparatus for Production of Ketones from Organic Acids, Employing Aerogel Catalysts. (S. S. Kistler, S. Swann, Jr., and E. G. Appel)

tion. This complex was decomposed by immersing in ice water and on fractionation yielded 69.5 g. of methyl naphthyl ketone, b.p. 156-160°C. under 9 mm. pressure. With the same amounts of naphthalene and acetyl chloride dissolved in 500 g. of nitrobenzene and the temperature between 8 and 10°C., 154 g. of methyl naphthyl ketone were secured in 9 hours. Instead of acyl chlorides, the corresponding carboxylic acid or acid anhydride may be employed in this type of reaction, provided that sufficient condensing agent is present. Thus, treatment of a mixture of 1 mole of acetic acid and 2 moles of toluene with 2.5 moles of aluminum chloride in an air stream at 105°C. was said to give an 80 per cent yield of *p*-methylacetophenone.[169] Condensation of 1 mole of acetic anhydride with 3 moles of toluene aided by 3 moles of aluminum chloride at 100°C. afforded a 75-85 per cent yield of 4-methylacetophenone.[170] Employment of an aluminum hydrosilicate catalyst at temperatures of 100-350°C. has been proposed for an analogous condensation of aromatic hydrocarbons with aromatic carboxylic acids.[171] Thus, *β*-naphthyl phenyl ketone may be produced from naphthalene and benzoic acid. The reaction is stated to be applicable to the production of ketones from heterocyclic compounds (except compounds of the pyridine series), including indole, thiophene and thionaphthene. Bruson and Stein[172] describe a method of producing alkylated aromatic ketones by reaction of an acylating agent with a mixture of a non-alkylated hydrocarbon, such as benzene, and an aliphatic halide in the presence of a condensing agent. In this manner the aliphatic chloride is said to interact with the cyclic compound to form a homologue of benzene. The latter then combines with the acetylating agent to produce the ketone. For example, benzene, amyl chloride and acetyl chloride may be treated with aluminum chloride at 100°C. to furnish amylphenyl methyl ketone, which boils at 121-123°C. at 3 mm. pressure. The latter compound has been suggested as a solvent in paint removers and as a lacquer ingredient.

PROPERTIES AND USES OF HIGHER KETONES

The homologues of acetone, in general, undergo the same reactions as the simplest ketone. They form addition products with hydrogen cyanide and sodium hydrogen sulphite, condensation products with hydroxylamine, hydrazine and phenylhydrazine, and may be oxidized to acids or reduced to alcohols.

Decomposition by Ultraviolet Radiation. The photochemical decompositions of methyl ethyl and methyl butyl ketone have been studied to determine the mechanism of each of these reactions.[173] The apparatus consisted of a quartz flask attached to a water-cooled condenser and spherical bulb (see Fig. 118). By completely evacuating the system and cooling the quartz flask in liquid air a sample of the ketone could be distilled into the flask from a side reservoir. The liquid air was then removed and the ketone allowed to reflux by slight heating. The vapor in the neck of the flask was illuminated by a vertical mercury lamp, furnishing lines of 3000-2200Å. The products of the photodecomposition were collected in the spherical bulb, from which samples were easily drawn off for analysis. In the case of methyl ethyl ketone it was concluded the reaction proceeds through two courses, one leading to ethane, propane, butane and carbon monoxide, the other to ethylene and acetaldehyde.

$$3CH_3COC_2H_5 \longrightarrow C_2H_6 + C_3H_8 + C_4H_{10} + 3CO$$
$$CH_3COC_2H_5 \longrightarrow C_2H_4 + CH_3CHO$$

With methyl butyl ketone the decomposition may be represented as:

$$CH_3CH_2CH_2CH_2COCH_3 \longrightarrow CH_3CH{=}CH_2 + CH_3COCH_3$$

These results were somewhat unexpected, in view of the fact that the carbonyl group is the one which absorbs the lines between 3500Å. and 2000Å. However, the carbonyl group apparently was not disrupted in the photochemical change since no oxygen was found in the decomposition products. It was assumed that the energy passes in whole or in part from the carbonyl link to some point in the hydrocarbon chain, with the result that carbon monoxide and a mixture of paraffins are produced in nearly equivalent proportion.

In all cases the break in the hydrocarbon chain was found to occur between the carbon atoms lying in positions a and β to the carbonyl group. It was therefore concluded that there is some sort of resonance between the carbonyl group and the carbon to carbon link in the a or β position, as a result of which the electronic energy of excitation of the former can be readily transferred to the latter. That free radicals play a part in the photochemical decomposition of ketones is indicated by the apparent formation of the propyl radical from diisopropyl ketone.[174a]

In cyclohexanone, 10 per cent solutions of methyl butyl ketone and of di-*n*-propyl ketone irradiated at 20°C. gave 98 per cent yields of propene and ethylene, respectively. However, at 100°C. the propyl ketone also formed ethane and carbon monoxide.[174b] From the behavior in gaseous phase and in solution, two types of reaction mechanism were postulated; one having activated molecules with relatively long lives which can be readily extinguished by solvent molecules; the other having molecules with such short lives that there is no time for intervention of solvent molecules between activation and reaction.

Other studies of photoreactions in solution show that the nature of the solvent influences the type of products formed.[174c] Mercury arc irradiation of liquid acetone or of its solution in carbon tetrachloride showed evidence of a reaction in which no gas was evolved. Products of treatment in hexane solution were more unsaturated (to bromine) than those obtained from acetone alone. On the other hand, a solution of the ketone in benzene did not show a photoreaction. Alcohol formation in hexane solution and in cyclohexane was noted; the product in the former case was supposedly dimethyl-*n*-hexylcarbinol and, in the latter, cyclohexyldimethylcarbinol.

Oxidation. The action of oxidizing agents on ketones leads to carboxylic acids or keto-aldehydes. Both saturated and halogen-substituted ketones may be converted in this manner. For example, methyl ethyl ketone subjected, in the liquid phase, to the action of gaseous oxygen at 75 to 105°C. under 4 atmospheres pressure is said to give acetic acid.[175] A catalyst consisting of a mixture of ferrous acetate and acetic acid is suggested. In the same manner, methyl isopropyl ketone is converted to a mixture of acetic and formic acids, cyclohexanone to adipic acid, and acetophenone to benzoic and formic acids. Oxidation of ketones in the presence of copper at a temperature of 350°C. is reported to give polyketones and keto-aldehydes rather than acids.[176]

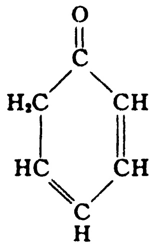
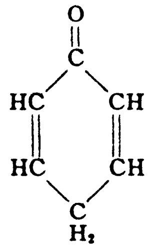
Electrolytic oxidation of cyclohexanone in dilute sulphuric acid, employing lead oxide and platinum electrodes, has produced maleic acid, a mixture of cyclic unsaturated ketones and a hydrocarbon, $C_{18}H_{12}$, presumed to be triphenylene.[177] It was thought that cyclohexanone first dehydrogenated to a mixture of two isomeric cyclohexadienones,



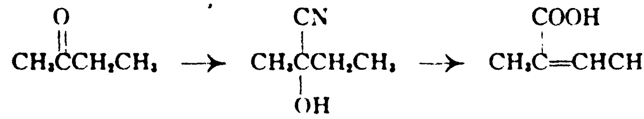
1,3-cyclohexadiene-6-one



1,4-cyclohexadiene-6-one

the latter being oxidized to maleic acid. Condensation of two molecules of 1,3-cyclohexadiene-6-one with elimination of water, and the corresponding condensation of three molecules of the ketone, gave respectively dicyclohexenedienehexenedienone and tricyclodihexenedienehexenedienone. Subsequent elimination of a molecule of water from the latter would explain the formation of triphenylene.

Addition of hydrogen cyanide to a ketone, and subsequent oxidation, yields an unsaturated acid. In one process, hydrogen cyanide is added to methyl ethyl ketone to form a ketone cyanohydrin which is then treated with sulphuric acid at 80-100°C. in the presence of hydroquinone. The latter is said to inhibit the formation of polymers of the cyanohydrin. The product is heated under reflux with water and ethanol to produce the ethyl ester of α-methyl crotonic acid together with the free acid.[178] In like manner acetophene may be converted into atropic



$$CH_3\overset{\overset{O}{\|}}{C}CH_2CH_3 \longrightarrow CH_3\underset{\underset{OH}{|}}{\overset{\overset{CN}{|}}{C}}CH_2CH_3 \longrightarrow CH_3\overset{\overset{COOH}{|}}{C}{=}CHCH_3$$

acid (α-phenylacrylic acid) and ethyl atropate.

A halogen-substituted ketone may be treated with an oxidizing agent to produce halogen-substituted acids from which hydroxy acids may be obtained. Thus, lactic acid may be secured from α-chloroethyl methyl ketone by this means.[179] In the procedure, concentrated nitric acid is blown, together with air, through a capillary tube into a well-stirred mixture of α-chloroethyl methyl ketone, chloropropionic acid and water maintained at 80-100°C. The products of the oxidation are said to be α-chloropropionic acid and small proportions of acetic acid and 1,1,1-dinitrochloroethane. Fractional distillation is employed to separate the chloropropionic acid, which boils at 186°C. The latter may be treated with aqueous caustic soda and heated in an autoclave at 130°C. for a period of 2 hours to form lactic acid (α-hydroxy propionic acid). The oxidation and subsequent hydrolysis may be represented as

$$CH_3CHClCOCH_3 \longrightarrow CH_3CHClCOOH \longrightarrow CH_3CH(OH)COOH$$

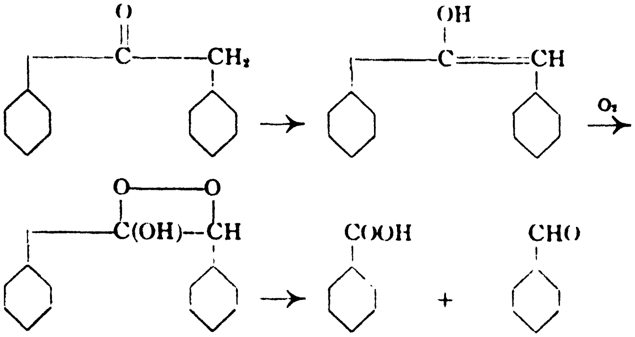
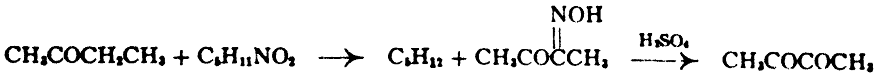
It is reported that halogen-substituted ketones containing two aromatic rings are autoxidized on exposure to air.[180] In one case benzyl-2-chlorophenyl ketone, which is a liquid, on standing slowly solidified and acquired a strong odor of benzaldehyde. The latter substance and, in addition, *o*-chlorobenzoic acid were isolated from the solid product. The suggested mechanism for the autoxidation was given as



Electrolytic Reduction. The electrolytic reduction of ketones has been reported to lead to the formation of straight-chain saturated hydrocarbons.[181] For example, a high yield of pentane is said to be obtained when 70 g. of methyl propyl ketone are dissolved in 70 cc. of 39 per cent sulphuric acid and reduced at 55-60°C., employing a cathode of cadmium and a current of 5 amperes.

Miscellaneous Reactions. Ketones containing only ethyl groups or higher react with zinc and organic halides to form metallic compounds which on hydrolysis yield tertiary alcohols.[182] Thus, dipropyl ketone, zinc and ethyl iodide give ethyl dipropyl carbinol. In like manner triethyl carbinol is made from diethyl ketone.

The action of aqueous solutions of nitrites upon methyl ethyl ketone has been utilized to prepare biacetyl.[182a] For example, the ketone mixed with amyl nitrite in the molecular ratio 1:2 and heated to 35-50°C. gives isonitrosoethyl methyl ketone. Subsequent treatment with dilute sulphuric acid and steam-distillation yields biacetyl.



$$CH_3COCH_2CH_3 + C_5H_{11}NO_2 \longrightarrow C_5H_{12} + CH_3CO\overset{\overset{NOH}{\|}}{C}CH_3 \xrightarrow{H_2SO_4} CH_3COCOCH_3$$

The effect of phosphorus pentachloride upon methyl ethyl ketone has been studied by Charpentier.[183] The reaction yielded 60 per cent of 2,2-dichlorobutane, b.p., 102°C., and 40 per cent of a liquid boiling between 60 and 65°C. The latter proved to be a mixture which could not be completely separated by repeated distillation. However, the two end fractions (b.p. 58.5-58.9°C. and b.p. 65-66°C.) were oxidized by potassium permanganate, the lower fraction furnishing propionic acid and the higher one acetic acid. It was therefore concluded that a portion of the 2,2-dichlorobutane lost a molecule of hydrogen chloride to form both 2-chloro-1-butene and 2-chloro-2-butene.

Treatment of diethyl ketone with a methanolic solution of calcium hypochlorite is reported to give a mixture of chloroform, acetic acid and propionic acid.[184] The reaction was explained on the basis of enolization of the ketone by alkali followed by reaction of the enolic hydroxyl group with calcium hypochlorite and isomerization to the α-chloroketone. The latter then follows the same procedure to form an α,α-dichloroketone.

$$\mathrm{CH_3CH_2COCH_2CH_3} \xrightarrow{\mathrm{Ca(OH)_2}} \mathrm{CH_3CH_2C(OH){=}CHCH_3} \xrightarrow{\mathrm{Ca(OCl)_2}}$$
$$\mathrm{CH_3CH_2COCl{=}CHCH_3} \longrightarrow \mathrm{CH_3CH_2COCHClCH_3} \longrightarrow \mathrm{CH_3CH_2COCCl_2CH_3}$$

USES OF HIGHER KETONES

Because of their selective solvent properties, some of the higher ketones have been recommended for dewaxing lubricating oil. The general procedure consists of mixing the ketone with the oil and cooling to between −10 and −23°C., in which range the ketone has excellent solvent action on the oil and substantially none on the wax. The latter is then removed by filtration or centrifuging. Among the ketones suggested for this purpose are included methyl ethyl,[185] a mixture of methyl ethyl and dipropyl,[186] methyl isobutyl,[187] acetophenone[188] and cyclohexanone.[189] Some ketones have been recommended as solvents for resins and cellulose acetate and nitrocellulose lacquers, among them being methyl ethyl ketone, methyl butyl ketone, methyl propyl ketone, methyl amyl ketone[190] and cyclohexanone.[191] Also, the higher ketones are employed in some cases in reactions with other substances, as, for example, phenols, to form synthetic resins.[192]

Chapter 19

Sulphur and Sulphur Compounds in Petroleum and Its Distillates. Their Occurrence, Chemical Properties and Possible Applications

All crude petroleums contain sulphur compounds, though the proportion of such bodies varies widely depending upon the source of the oil.[1] Pennsylvanian and Rumanian oils probably have the smallest amounts, being about 0.03 per cent or less. Some American oils, such as those from fields in Texas, possess about 1 to 2.5 per cent, and the highest sulphur content (about 5 per cent) is generally associated with Mexican crudes. Practically all types of sulphur derivatives have been isolated from mineral oil distillates. Thus, Kazarnovskaya and Sosnina[2] state they found elemental sulphur, hydrogen sulphide, mercaptans, thioethers, disulphides and thiophenes in the gasoline and kerosene fractions of Russian crudes. The presence of amyl mercaptan and *sec*-hexyl mercaptan in the gasoline cut boiling at 113-155°C. (from Japanese shale oil) has been reported,[3] and a lower-boiling (below 40°C.) distillate contained dimethyl sulphide and ethyl mercaptan.[4]

One objection to sulphur or its derivatives in petroleum products is the corrosive action on metals. This may occur when the distillates are stored, or from the sulphur dioxide (and subsequent sulphuric acid) formed when the liquids are employed as fuels in internal combustion engines.[5] There has been considerable controversy as to the maximum, permissible sulphur content of refined oils, particularly for gasoline and kerosene. In spite of the wide differences of opinions on this question, in the United States an almost universal value of 0.1 per cent total sulphur was adopted. In addition the fuel should be non-corrosive to copper, thus indicating the absence or only a very small proportion of elemental sulphur.

The effect of sulphur derivatives on the color stability of gasolines was investigated by Egloff, Morrell, Benedict and Wirth.[6] With straight-run distillates, the addition of ethyl, *n*-propyl or *n*-amyl mercaptans had little effect on the color when the sample was exposed to light from a carbon arc lamp. (See Fig. 119.) When the corresponding disulphides were incorporated, however, the gasoline became cloudy after exposure. In the case of cracked distillates or these blended with straight-run fractions, both types of sulphur compounds effected a development of haze and a deepening in color. The latter phenomena were most marked with elemental sulphur in cracked gasolines. Both haze and color could be removed from straight-run products by filtration through paper, thus indicating that suspended particles were responsible for these effects. Filtration (after exposure) of cracked spirits clarified, but only slightly improved, color, showing that in this instance

soluble colored compounds had been formed. Substitution of individual hydrocarbons, viz., *n*-heptane, 2,2,4-trimethylpentane, octene-2, diisobutylene, cyclohexene, cyclopentadiene, benzene and toluene for gasolines led to analogous results.[7] In the presence of elemental sulphur all the hydrocarbons developed color on exposure to light, and all reacted with this element. The olefins and cycloolefins furnished hydrogen sulphide and mercaptans, while the paraffins, cycloparaffins and aromatics gave hydrogen sulphide and thioethers. It was also found that on dissolving *n*-propyl disulphide in the hydrocarbons and exposing the solutions to light and oxygen that sulphur dioxide and trioxide were formed. If the tests were carried out in an atmosphere of nitrogen or hydrogen the development of mercaptans was observed.

[7] J. C. Morrell, W. L. Benedict and G. Egloff, *Ind. Eng. Chem.*, 1936, **28**, 448; *Chem. Abs.*, 1936, **30**, 3979.

Schulze and Buell[8] have shown that organic sulphur compounds reduce the lead susceptibility of motor fuels, i.e., the increase in octane number on the addition of lead tetraethyl is less per unit volume of reagent the greater the proportion of sulphur in the fuel. In general, alkyl disulphides are the most harmful in this respect and thioethers less so, while cyclic compounds exhibit the least effect. Comparison of aliphatic sulphides and disulphides indicated that reduction of octane number was greater with the homologues of higher molecular weights and with the branched-chain isomers. Results obtained with some disulphides are given in Table 102.

TABLE 102.—*Effect of Disulphides on Lead Susceptibility of Gasoline.*

Compound	Wt. % Sulphur Added	Octane Number at cc. of Lead Tetraethyl per Gallon 0	1	2	3	6
Reference fuel	—	51.0	63.5	70.7	74.7	79.5
Methyl disulphide	0.39	48.9	52.4	53.0	56.2	64.5
Ethyl disulphide	0.41	48.4	52.4	55.6	58.2	64.5
n-Butyl disulphide	0.064	50.6	58.7	63.6	66.5	72.7
sec-Butyl disulphide	0.028	50.3	59.6	65.8	69.5	75.8
ter-Butyl disulphide	0.028	50.6	59.6	65.4	69.1	75.6
Benzyl disulphide	0.034	49.3	58.8	64.6	68.6	76.2
Diphenyl disulphide	0.036	49.9	59.6	66.1	69.8	76.6

Schulze and Buell also found that reducing the sulphur content of a natural gasoline from 0.037 to 0.008 per cent increased the octane number by two points. Furthermore, the addition of 1 cc. of lead tetraethyl to the desulphurized fuel yielded a product having an 81 octane number as compared with 75.6 for the untreated gasoline and same quantity of lead.

Because of the above mentioned effects, corrosion, light instability, and change in anti-knock property of fuel, removal of at least part of the sulphur in some types of petroleum distillates is practically imperative. The resulting accumulation of sulphur-containing substances as by-products of refining operations has stimulated efforts towards their utilization. For this reason the chemistry of the various types of sulphur derivatives found in petroleum and their possible applications are of interest.

HYDROGEN SULPHIDE

Because of its well-known highly toxic property and its corrosive action on metals,[9] the elimination of hydrogen sulphide from petroleum distillates and refinery gases, particularly those from high-sulphur crudes, is of importance. In the case of distillates, extraction with solutions of alkalies, such as sodium hydroxide or carbonate, or with aqueous suspensions of less soluble metallic hydroxides, e.g., magnesium hydroxide, is usually sufficient.[10] Crosby and Carney[11] suggest the use of aqueous suspensions of lime, operation being conducted under pressure to prevent the formation of emulsions. In the procedure, the distillate and suspension of lime are admixed in a series of U-tubes (Fig. 120) under a gage pressure of 20-45 lbs. per sq. in. In this manner, hydrogen sulphide is said to be converted to calcium hydrogen sulphide. After a contact period of 1 minute the mixture is conducted to a separator. In the latter three layers are formed, the upper layer consisting of the distillate, the middle of unused lime, and the lower of calcium hydrogen sulphide. The distillate may then be scrubbed with dilute caustic soda to remove the remaining hydrogen sulphide. Unused lime may be recycled, while the calcium hydrogen sulphide is discarded or employed in preparing fresh lime suspension. Vacuum flashing of kerosene, to eliminate 60-90 per cent of dissolved hydrogen sulphide, followed by caustic washing is proposed by Woods.[12] Another method consists in agitating the distillate with a water solution of sulphur dioxide, whereby hydrogen sulphide is oxidized to elemental sulphur.[13] The resulting aqueous suspension of sulphur is then separated and added to a sour distillate, which has been subjected to treatment with sodium plumbite, to effect sweetening (*q.v.*).

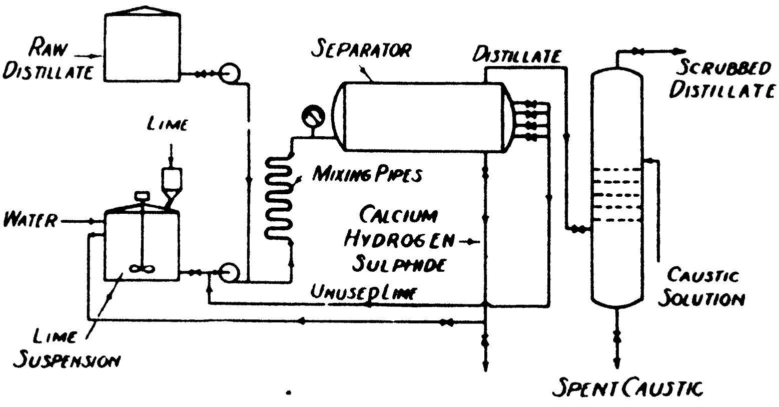

FIG. 120.—Sketch of Method for Removal of Hydrogen Sulphide by Treatment of Petroleum Distillates with Lime Suspensions. (R. H. Crosby and B. R. Carney)

Although hydrogen sulphide may be removed from gaseous mixtures by washing with water[14] (under pressure), aqueous inorganic alkalies are more often employed for this purpose. In the case of sodium carbonate the reaction is

$$Na_2CO_3 + H_2S \longrightarrow NaHS + NaHCO_3$$

Recovery of hydrogen sulphide from the spent liquor may be accomplished by dissolving sufficient carbon dioxide in it until all sodium carbonate is converted to the bicarbonate and subjecting the solution to reduced pressure, heating slightly if necessary.[15] Stronger heating then liberates carbon dioxide and changes sodium bicarbonate to carbonate. Rosenstein and Kramer[16] suggest washing gases with a solution of tripotassium phosphate. Hydrogen sulphide may be regenerated by heating the extraction medium. Various types of organic bases have been recommended also, such as triethanolamine,[17] N-ethylglycocoll and sodium salts of dimethyl-N-anthranilic acid,[18] ethylenediamine, quinoline, pyridine, or their homologues[19] (in organic solvents), or tri- or tetramines,[20] e.g., monohydroxymethyldiethylenetriamine.

If the gases contain both hydrogen sulphide and carbon disulphide and aqueous calcium hydroxide be employed as the extraction medium then calcium thiocarbonate is formed.[21] The reactions occurring in this instance may be indicated in the following manner:

$$Ca(OH)_2 \xrightarrow{H_2S} Ca(SH)_2 \xrightarrow{H_2O} Ca(OH)(SH) \xrightarrow{CS_2} Ca(OH)_2 \cdot CaCS_3$$

Concentrated aqueous solutions of sodium phenolates or sodium salts of tar acids are proposed by Shaw[22] as extraction media. The phenolates from a shale tar (boiling 200-300°C.) are reported to absorb hydrogen sulphide three times as rapidly as carbon dioxide, thus affording a method for the separation of these gases.[23] Another procedure consists in passing the gases through an aqueous suspension of manganese oxide or hydroxide, whereby manganese sulphide is formed and also carbonate, if carbon dioxide be present.[24] Treatment of the mixed manganese compounds with steam results in hydrolysis of the sulphide and liberation of hydrogen sulphide. On heating the residue, out of contact with air, the carbonate is decomposed into manganese oxide and carbon dioxide.

Alkaline solutions of the oxides or salts of arsenic, antimony or tin, have been recommended as extracting agents for hydrogen sulphide.[25] A two-stage process involving partial removal of the sulphide by such solutions and elimination of residual hydrogen sulphide with aqueous ammonium sulphite is described by Eymann.[26] In other instances aqueous suspensions of metallic hydroxides, e.g., those of iron, zinc, or manganese, may be employed in the first stage, and an aqueous solution of a thionate in the second stage.[27] The use of ammonium bisulphite solutions at 60-100°C. has been proposed.[28]

the pressure over the latter.[33] In this manner the sulphide is said to be separated together with some of the lower boiling hydrocarbons. Rectification of the gaseous portion is then effected to recover the hydrocarbon present. The use of muddy iron ore has been suggested in another method.[34] Chlorine may also be employed to replace the sulphur in hydrogen sulphide.[35] The sulphur is then treated at 112-170°C. with hydrogen sulphide. Pure sulphur is said to be furnished in this way.

CATALYTIC OXIDATION OF HYDROGEN SULPHIDE

The ease with which hydrogen sulphide is oxidized to water and elemental sulphur furnishes a basis for the removal of this compound from either liquid or gaseous mixtures. For example, aqueous liquids used in scrubbing gases are caused to flow simultaneously with a stream of air (or oxygen) over coke or pumice on which a catalyst is supported.[36] The latter may consist of metallic hydroxides or oxides, such as those of titanium, vanadium, chromium, iron, molybdenum or tungsten. When water contains dissolved or suspended low-boiling organic compounds, e.g., benzene, it can be conducted through two filters of activated carbon, the first of which adsorbs sulphur or sulphur compounds, and the second the organic substances.[37] The liquid is treated with oxygen (or other oxidizing agents) before passage through the first filter.

Preferential oxidation of hydrogen sulphide in producer gas[38] or in gases from hydrogenation or cracking operations[39] may be effected in the presence of activated carbon. Aqueous ammonium sulphide is employed for extraction of elemental sulphur from the catalyst and reactivation of the latter carried out at 110-120°C.[40] Kazarnovskii and Pisarev[41] suggest adding oxygen to the extent of 25 per cent excess over that required for oxidation of hydrogen sulphide, 3 per cent ammonia, and then heating the mixture to 70-75°C. Afterwards the gaseous mixture is conducted over carbon at 115-120°C. It is reported that iodine-treated activated charcoal has a greater adsorptive power for hydrogen sulphide (and also sulphur dioxide) than pure activated charcoal.[42]

A process developed by Bacon[43] includes bringing gases, containing hydrogen sulphide as an impurity, into contact with alkaline solutions in the presence of oxygen. A mixture of zinc or iron salts may be added as catalyst to the alkali and operation conducted under pressure.

PROPERTIES OF HYDROGEN SULPHIDE

Under atmospheric pressure and ordinary temperatures, hydrogen sulphide is a gas. It can be condensed to a liquid boiling at —59.6°C. and freezing at —82.9°C. The critical temperature and pressure of this sulphide are 100.4°C. and 88.9 atmospheres, respectively.[44] The density of the liquid at temperatures ranging from —81° to 58°C. was determined by Baxter, Burrage and Tanner,[45] who found the value at the lower temperature was 0.938 and 0.680 at the higher temperature. The results of these investigators are shown graphically in Fig. 123. The solubility of hydrogen sulphide in hydrocarbons, e.g., hexane, benzene, or toluene, is generally greater than in water. The distribution coefficients,[46] at various temperatures, of this sulphide between benzene and water are given in Table 103.

TABLE 103.—*Distribution Coefficients of Hydrogen Sulphide between Benzene and Water.*

Temperature, °C.	Distribution Coefficient
6	5.3
12	5.55
20	5.7
30	5.75
40	5.81

The solubility of different types of hydrocarbons in liquid hydrogen sulphide was investigated by Terres and Vollmer.[47] They noted that at 0°C. paraffins, aromatics (such as benzene and toluene), hydroaromatics and heterocyclic compounds (e.g., quinoline) were miscible in all proportions. Other compounds, for example, phenol, *o*-cresol and dicyclic hydrocarbons (naphthalene) exhibited a high solubility in the liquid. All the substances investigated formed only one liquid phase with hydrogen sulphide and in no case was a miscibility gap observed. Toluene, phenol and quinoline formed intermediate compounds of the types, $2C_6H_5CH_3 \cdot H_2S$, $2C_6H_5OH \cdot H_2S$ and $C_9H_7N \cdot H_2S$, respectively. Octadecane and hexahydrobenzene yielded solid solutions with hydrogen sulphide.

Miscellaneous Reactions of Hydrogen Sulphide. Combination of olefins and hydrogen sulphide at high temperatures (650-725°C.) in the presence of catalysts furnishes a variety of products, including mercaptans, thiophene and its homologues, thioethers and carbon disulphide. At lower temperatures (200-300°C.) mainly mercaptans are formed.[48] Propene and hydrogen sulphide, according to Barr and Keyes,[49] reacted, when using a nickel sulphide catalyst, to yield isopropyl and *n*-propyl mercaptans in the ratio of approximately 2:1. The temperature range was 200-300°C., and larger yields were obtained at the lower temperatures. Some of the results of these investigators are given in Table 104.

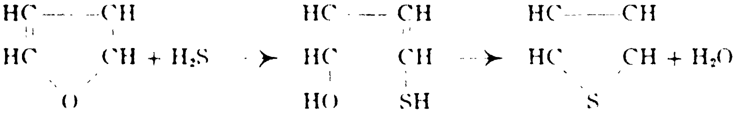
Union of hydrogen sulphide and isobutene may be effected in the following manner:[50] The olefin is dissolved in cold 75-80 per cent sulphuric acid, yielding a mixture of *ter*-butyl acid sulphate and di-*ter*-butyl sulphate. A rapid stream of hydrogen sulphide is passed into these sulphates whereupon an oily layer of mercaptans is formed. After completion of the reaction and dilution of the mixture with water, the upper layer is removed, washed with water, dried and distilled. It consists essentially of *ter*-butyl mercaptan.

Analysis indicated that a mixture of 2-thiol-2-methylbutene-3 and 2,3-dithiol-2-methylbutane

$$(CH_3)_2C(SH)CH{=}CH_2 \quad \text{and} \quad (CH_3)_2C(SH)CH(SH)CH_3$$

respectively, resulted from the action of hydrogen sulphide on isoprene at 96°C., using ferric oxide as a catalyst.[51] The former compound was readily oxidized by peracetic acid. Further investigation was precluded by the odor of the products.

Nenitzescu and Scarlatescu[52] report that passage of gaseous hydrogen sulphide and ethylene oxide through a Raschig column results in the formation of β,β'-dihydroxyethyl sulphide, provided the rings have been moistened previously with some of the product. Otherwise reaction does not appear to take place. With furan (another cyclic oxide), at 450°C. and aluminum oxide as a catalyst, substitution of oxygen by sulphur occurs and thiophene is formed.[53] It is suggested in this instance that splitting of the ring takes place with the production of an intermediate hydroxy mercaptan which then undergoes dehydration and cyclization.



Another example of the replacement of oxygen by sulphur (accompanied by ring-formation) is the preparation of *sym*-trithiane from formaldehyde and hydrogen sulphide.[54]

Decomposition of hydrogen sulphide (at −15° to 18°C.) in a high frequency discharge is apparently a first order reaction, proceeding according to the equation

$$dc/dt = K(A - C)$$

in which K is a measure of the speed and A is the limiting concentration of hydrogen sulphide.[55] The values of A and K at various temperatures are:

Temp. °C.	Values of: A	K
18	14 0	3 750
4	57 3	1 034
− 5	73	0 961
−15	86 0	0 250

Polysulphides are probably formed as intermediate products and the rate at which they further disintegrate (wall-reaction) into various sulphur polymers determines the constant K.

UTILIZATION OF HYDROGEN SULPHIDE

This gaseous sulphide is said to be a cheap and economical raw material for the manufacture of sulphuric acid, yields of the latter as high as 98 per cent having been reported.[55a] The gas is burned with excess air to give water and sulphur dioxide. The latter, mixed with air or oxygen, is converted into sulphur trioxide by passage over a vanadium oxide or tin dioxide and chromium oxide catalyst at 350-400°C. Absorption of the trioxide in water yields sulphuric acid. A flow diagram of one such method is indicated in Fig. 124. This process is applicable to mixed gases containing hydrogen sulphide, such as those from coke ovens or hydrogenation operations.

When mixed with inert gases, complete conversion of the sulphide into sulphuric acid is not economically feasible.[56] For instance, with a gas whose composition is 30 per cent hydrogen sulphide and 70 per cent carbon dioxide only 70 per cent removal of the former (as sulphuric acid) is considered practicable.

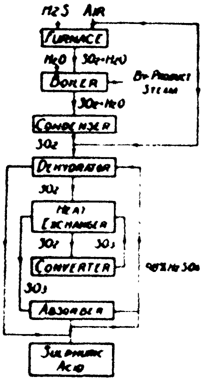

FIG. 124.
Flow Diagram for Manufacture of Sulphuric Acid from Hydrogen Sulphide. (I. Hechenbleikner, T. C. Oliver and S. F. Spangler)

Another method of utilization comprises treatment with halogens (chlorine or bromine) in the presence of sulphur mono- or dichloride.[57] The hydrogen halide thus formed is afterwards washed with a hydrocarbon, e.g., xylene. Drosdoff and Truog[58] suggest stripping iron oxide coatings from minerals by suspending the sample in water, treating with hydrogen sulphide, and then with 0.05N hydrochloric acid. The ripening of alkali-cellulose by air or a gas containing oxygen is said to be accelerated by the presence of an alkali sulphide, e.g., sodium sulphide.[59]

Mild oxidation of hydrogen sulphide, particularly in the form of its alkali salts, gives rise to thiosulphates. Aqueous solutions of these alkali salts may be obtained by the methods previously described for the purification of gaseous mixtures or of liquids. For example, in the Koppers process in which gases are scrubbed with sodium carbonate solution (for hydrogen sulphide removal) and the latter regenerated by aeration with air (or other oxidizing gases) some thiosulphate is formed.[60] After sufficient accumulation of this compound has taken place it may be recovered from the spent alkali. According to Hasenbach,[61] passage of hydrogen sulphide over sodium sulphide at 300°C. yields sodium hydrosulphide. Treatment of the latter with air at 100-150°C. gives sodium thiosulphate.

$$2NaHS + 2O_2 \longrightarrow Na_2S_2O_3 + H_2O$$

Meschorer[62] recommends the use of manganese dioxide in the oxidation of aqueous sodium sulphide. This procedure, however, furnishes large proportions of sodium hydroxide and carbonate as by-products. Larger yields of thiosulphate are obtained by air-blowing concentrated sodium sulphide solutions (61 per cent) and employing finely divided activated charcoal as the catalyst.[63] In this instance reaction is vigorous and good temperature control is necessary. Separation of any carbonate and hydroxide may be effected by recrystallization of the thiosulphate and extraction with alcohol.

In place of oxygen, sulphur dioxide (or sulphurous acid or its salts) may be used as the oxidizing agent. For example, aqueous sodium sulphide and sulphur dioxide are conducted simultaneously into a solution of sodium sulphite maintained at 60°C.[64] The delivery rates of the reactants are such that sulphur dioxide is always slightly in excess and neither hydrogen sulphide nor sulphur is formed.

$$2Na_2S + 3SO_2 + Na_2SO_3 \longrightarrow 3Na_2S_2O_3$$

Sodium bisulphite may be used instead of the sulphite.[64a] Or the gas containing

$$2Na_2S + 2NaHSO_3 + 2SO_2 \longrightarrow 3Na_2S_2O_3 + H_2O$$

hydrogen sulphide can be treated with a solution of sodium sulphite and bisulphite at 70-75°C.[65]

$$2Na_2SO_3 + 2NaHSO_3 + 2H_2S \longrightarrow 3Na_2S_2O_3 + 3H_2O$$

Another variation comprises reacting sodium polysulphide with sodium bisulphite at 60°C.[65a]

$$2Na_2S_2 + 6NaHSO_3 \longrightarrow 5Na_2S_2O_3 + 3H_2O$$

Foerster and Mommsen[66] have shown that a large yield of thiosulphate is easily obtained on mixing aqueous sodium hydrogen sulphide and bisulphite in the molecular ratios of 2:1. Also sodium sulphide and sulphur dioxide

$$2NaHS + 4NaHSO_3 \longrightarrow Na_2S_2O_3 + 3H_2O$$

or sodium sulphite and hydrogen sulphide furnish sodium thiosulphate provided the acidity of the reaction mixtures is controlled. This can be done by adding initially sufficient alkali hydroxide to secure formation of sodium bisulphite or hydrosulphide, as required. It is interesting to note that an ore flotation agent may be secured by the interaction of rosin and hydrogen sulphide at 80°C. in the absence of conditions which would promote oxidation.[66a]

DETECTION OF HYDROGEN SULPHIDE

Tests for this compound depend upon its color reaction with reagents, particularly metallic salts. One type of detector consists of filter paper moistened with a solution of lead acetate (10 g.) in 50 per cent aqueous glycerol (100 cc.)[66b] The stain obtained when this treated paper is exposed to the gaseaus sample is reported to be sensitive to 1 part of hydrogen sulphide in 80,000 parts of gas. Another type is essentially a glass tube packed with granules of activated aluminum oxide coated with silver cyanide or lead acetate.[67] Gas is conducted through the tube and the distance over which a color change occurs is a measure of the proportion of hydrogen sulphide. This detector operates at temperatures of —22° to +25°C. and with samples containing 0.0025-0.05 per cent hydrogen sulphide. In another procedure the hydrogen sulphide is absorbed in aqueous silver nitrate, containing 1 per cent of the silver salt.[68] Silver sulphide is precipitated, and dissolved in potassium cyanide solution. On treating the latter with sodium plumbite, colloidal lead sulphide is formed, and its color compared with standard solutions. Bell and Hall[69] recommend a dilute aqueous solution of sodium nitroprusside. In this instance the color changes to pink, mauve, or deep violet depending upon the quantity of sulphide which passes through it.

Landgraf[70] suggests pellets of manganese dioxide coated with sirupy phosphoric acid as an absorption medium in gas analysis. A method for determining the rate of absorption of hydrogen sulphide, as well as the total amount, by gas-purifying materials is described by Brückner.[71] One-half to one gram of the material to be tested is placed in a 500 cc. reaction flask, and then a measured volume of hydrogen sulphide is introduced. The container is kept at 20°C. and the decrease in pressure with time is recorded. Afterwards the sulphur content of the spent absorption agent is determined by treatment with sodium sulphite which is converted to thiosulphate.

ELEMENTAL SULPHUR

The presence of elemental sulphur in petroleum distillates may be attributed to decomposition of complex sulphur compounds during distillation operations, oxidation of dissolved hydrogen sulphide, or employment of an excess of this element in doctor sweetening (*q.v.*). Probably the chief objection to it in low-boiling distillates (gasoline and kerosene) is its corrosive action on metals. A number of

procedures, involving the use of alkalies, solid alkali sulphides, and metallic elements (sodium or nickel), have been suggested for its removal from petroleum fractions.[72] This element (sulphur) can be extracted also with aqueous solutions of alkali polysulphides, provided the composition of the latter contains less sulphur than that corresponding to the tetrasulphide.[73]

Reaction of petroleum hydrocarbons with sulphur gives rise to a variety of products. In many instances heterocyclic compounds, e.g., thiophene, are obtained when unsaturated hydrocarbons are employed. For example, acetylene and sulphur at 290-390°C. yield not only thiophene but also thiophenol, carbon disulphide and hydrogen sulphide.[74] According to Hessle,[75] substitution of cracked distillates for acetylene and use of lower temperatures (200-250°C.) results in thiophene derivatives. Oxides or hydroxides of iron, nickel, cobalt, manganese, chromium or the alkali earth metals may be used as contact agents. The reaction products may be separated by fractional distillation and sulphonation of these is reported to furnish materials which can be employed in therapeutic and cosmetic preparations. Distillation of higher-boiling fractions, e.g., asphalt oil, mixed with sulphur until the loss in weight is 22-25 per cent, yields ingredients applicable in coating compositions.[76]

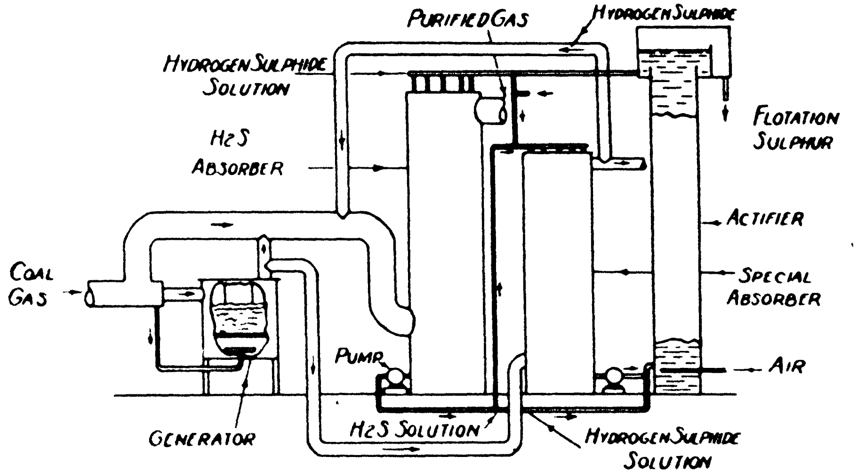

FIG. 125—Sketch of Apparatus for Making Colloidal Sulphur from Hydrogen Sulphide. (C. J. Ramsburg)

Heating sulphur with a hydrocarbon oil or in a current of coal gas and absorption of the resulting hydrogen sulphide by ferric oxides or an aqueous solution of sodium hydroxide followed by treatment with an oxygen-containing gas furnishes colloidal sulphur.[77] The latter may be withdrawn as a froth (Fig. 125) while the partially fouled solution of ferric oxides containing some hydrogen sulphide is employed as an absorption agent for further quantities of the sulphides. Complete conversion of mineral oil (at 400-700°C.) to hydrogen sulphide and carbon disulphide is said to be attained if the heating operation is carried out in a cast iron retort packed with aluminum or stainless steel turnings.[78]

Combination of olefins and sulphur may be effected by submitting the hydrocarbon to the simultaneous action of hydrogen sulphide and the element.[79] Basic substances, such as ammonia, amines, piperidine and substituted guanidines or thiuram sulphides, can be used as carriers for sulphur. Particular applications of this procedure are the vulcanization of rubber or the preparation of factice.

An investigation of the reaction between sulphur and benzene, at 80°C., in the presence of aluminum chloride was made by Dougherty and Hammond.[80] These investigators found that the products were diphenyl sulphide and thianthrene, and the ratio in which these two compounds were formed depended to a marked degree upon the proportion of aluminum chloride employed. When the amounts of reactants were kept constant, increasing the quantity of aluminum chloride to 0.2-0.3 mole increased the yield of both sulphur compounds. From there on the yield of diphenyl sulphide increased while that of thianthrene decreased. This is illustrated by the results given in Table 105.

TABLE 105.—*Yields of Diphenyl Sulphide and Thianthrene from Benzene (200 cc.) and Sulphur (32 g.).*

Moles of Aluminum Chloride	Moles of Diphenyl Sulphide	Moles of Thianthrene
0.1	0.032	0.1
0.2	0.062	0.179
0.3	0.147	0.125
0.4	0.215	0.118
0.5	0.310	0.068
0.6	0.310	0.068
0.8	0.361	0.046
1.0	0.350	0.053

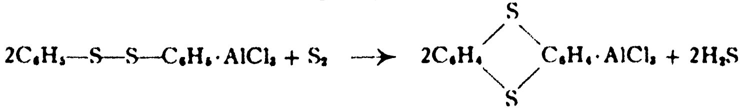
Reactions for the formation of these two compounds can be represented as follows: For diphenyl sulphide

$$S_2 \cdot AlCl_3 + C_6H_6 \cdot AlCl_3 \longrightarrow C_6H_5{-}S{-}S{-}H \cdot AlCl_3 + AlCl_3$$

$$C_6H_5{-}S{-}S{-}H \cdot AlCl_3 + C_6H_6 \cdot AlCl_3 \longrightarrow C_6H_5{-}S{-}C_6H_5 \cdot AlCl_3 + AlCl_3 + H_2S$$

and for thianthrene

$$2C_6H_5{-}S{-}C_6H_5 \cdot AlCl_3 + S_2 \longrightarrow 2C_6H_5{-}S{-}S{-}C_6H_5 \cdot AlCl_3$$



With aromatic ketones, in the absence of catalysts, the course of the reaction appears to be governed largely by the temperature. For example, benzophenone and sulphur at 155-175°C. (in an atmosphere of nitrogen) furnish biphenylacyl, and at 180-210°C. thioindigo is also obtained.[81] In a similar manner, the products from α- or β-acetonaphthone are 1,2- and 2,1-naphthothioindigo. Also coumarin may be treated with sulphur at 220-230°C. for a period of 48 hours to furnish a thiophene derivative ($C_{18}H_8O_4S$), which melts at 331-331.5°C.[82]

When sulphur is added to potassamide dissolved in liquid ammonia, a yellow precipitate is first formed which redissolves on the further addition of sulphur.[83] The reaction appears to be represented by

$$6KNH_2 + 3S \longrightarrow S(NK)_2 \cdot NH_3 + K_2S \text{ (insoluble)}$$

or if carried out rapidly

$$6KNH_2 + 12S \longrightarrow S_4(NK)_2 + 4NH_3 + K_2S_4$$

Incorporation of sulphur slowly also yields some potassium trisulphide.

In studying the action of carbon tetrachloride on sulphur,[84] chlorides of iron, aluminum or copper were employed as catalysts and the temperature maintained at 120°C. It was stated that the reaction results in the production of carbon disulphide and sulphur monochloride, and that the two latter substances also interact to give the original reactants. Equilibrium was said to be represented as:

$$6S + CCl_4 \underset{77.4\%}{\overset{22.4\%}{\rightleftarrows}} CS_2 + 2S_2Cl_2$$

Although, as previously mentioned, the presence of elemental sulphur in gasoline is objectionable, nevertheless addition of a small proportion (0.01-0.05 per cent) of this element, or of selenium or tellurium, to lubricating oils is recommended.[85] A stable emulsion of sulphur, particularly in oils intended for cutting operations, is obtained by employing sodium oleate as the emulsifying agent.[86] In other instances, sulphurized lubricants are prepared by heating the oil and sulphur to 300-500°F. under a pressure of 75-150 pounds per square inch.[87] Prior to reaction with sulphur, oxidized paraffin wax may be incorporated with the liquid.[88]

MERCAPTANS

Sulphur-containing compounds of this type, because of the presence of the -SH group, are characterized by their acidic properties.[89] Reaction with alkalies to form mercaptides is well-known and serves as a basis for extraction of mercaptans from petroleum distillates. The distribution coefficients of some low-boiling mercaptans between a cracked naphtha (boiling 83-338°F.) and dilute aqueous caustic soda (0.417 lb. per gal.) were determined by Happel and Robertson.[90]

[90] J. Happel and D. W. Robertson, *Ind. Eng. Chem.*, 1935, **27**, 941; *Chem. Abs.*, 1935, **29**, 6748; *Brit. Chem. Abs.* **B**, 1935, 887; *J. Inst. Pet. Tech.*, 1935, **21**, 369A.

Their method was as follows: The cracked naphtha, before and after shaking with half its volume of the alkali solution, was fractionated into several cuts, and the mercaptan content of each cut determined. From the data so obtained, distribution coefficients (Table 106) were calculated.

TABLE 106.—*Mercaptan Distribution Coefficients between Cracked Naphtha and Aqueous Alkali.*

Cut	End Point °F.	Mercaptan	Distribution Coefficient
1	65	Methyl	213
2	125	Ethyl	80.0
3	180	Propyl	10.7
4	235	Butyl	3.0
5	280	Amyl	1.0
6	Residue	Hexyl	0

These investigators also show that 2-stage countercurrent extraction with more dilute alkali (0.05 lb. sodium hydroxide per gal.) is effective in removing mercaptans. In the first stage the naphtha was bubbled through partially spent alkali and in the second stage the washed distillate was treated with fresh alkali in a centrifugal pump. The mercaptan contents of the naphtha before and after each treating stage are detailed in Table 107.

TABLE 107.—*Countercurrent Treating of Sour Naphtha with Aqueous Alkali.*

	Mercaptan Sulphur (lb./gal.)		
Mercaptan	Raw Naphtha	1st Stage	2nd Stage
Methyl	0.0077	0.0036	0.0009
Ethyl	0.0027	0.0014	0.0005
Propyl	0.0014	0.0013	0.0007
Butyl	0.0005	0.0006	0.0004
Amyl	0.0002	0.0002	0.0002
Hexyl	0.0003	0.0003	0.0003
Total	0.0128	0.0074	0.0030

Separation of cracked petroleum distillates into fractions containing predominately one type of mercaptans is described by Lacomble.[91] For example, a cut boiling at −12° to −7°C. was found to contain only methyl mercaptan and only ethyl mercaptan was present in a fraction boiling about 15-21°C.

Regeneration of alkali solutions, employed for the extraction of mercaptans from petroleum oils, may be accomplished by washing with an immiscible liquid in which elemental sulphur is dissolved.[92] The liquid should be a solvent for the reaction product of sulphur and the mercaptide-containing solution. Another procedure involves the use of an oxidizing agent such as sodium hypochlorite, whereby mercaptans are converted into disulphides.[93] Blowing air through the hot spent alkali is suggested also.[94]

Alcoholic, instead of aqueous, solutions of alkalies may be employed as extraction agents.[95] In this instance sufficient water is added to the alcohol to render it immiscible with the petroleum distillate. After extraction, the solvent is removed by distillation and the residue treated with steam to effect hydrolysis of the mercaptides and distillation of the resulting mercaptans.[96] Another method of recovering mercaptans comprises contacting the vapors of cracked distillates with aqueous sodium plumbite whereby lead mercaptides are formed and hydrolyzing the latter with steam.[97]

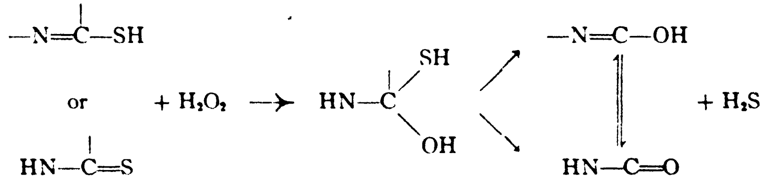
Properties of Mercaptans. As previously mentioned, the presence of the -SH group is the explanation offered for the acidic properties of mercaptans. A well-known method for their preparation is reaction of alkyl halides with alkali hydrosulphides. Application of this procedure to dihalides, however, results not only in the formation of bodies containing two -SH groups but also sulphide mercaptans.[98] For example, distillation of the product from ethylene chloride and potassium hydrosulphide gave a 45-55 per cent yield of ethylene mercaptan, $C_2H_4(SH)_2$, 16 per cent of the sulphide derivative, $HSC_2H_4SC_2H_4SH$, and 1.5 per cent of the disulphide, $HSC_2H_4SC_2H_4SC_2H_4SH$. In addition, dithiane and polymeric sulphur compounds were obtained.

Mercaptans react with many types of reagents, such as oxidizing agents (oxygen, sulphur and halogens) to form disulphides, with aldehydes and ketones to give mercaptals and mercaptoles, respectively, and with acids to yield esters.[99] Being derivatives of hydrogen sulphide probably accounts for their disagreeable odor[100] and toxicity,[101] particularly of lower-boiling mercaptans.

Oxidation. Although mild oxidation results in disulphides, more vigorous reaction furnishes sulphonic acids. Thus, *ter*-amyl mercaptan and hydrogen peroxide give the hygroscopic *ter*-pentanesulphonic acid,[102] and 2,2'-dimercaptodiethyl ether and the same reagent yield the corresponding disulphonic acid.[103] Kitamura[104] reports that when the sulphur atom is joined to a carbon atom with a double bond, oxygenated products are obtained in place of disulphides on treatment with hydrogen peroxide in an alkaline medium. He represents the reaction as



Hydrogen sulphide formed during the reaction is probably oxidized to sulphuric acid. Herrera[105] considers the reaction to be

Thiobenzylamide or thioacetic acid and hydrogen peroxide gave the corresponding oxygenated compounds, but the peroxide had no effect on benzyl sulphide or disulphide.

Preparation of Thioethers. At elevated temperature and in the presence of catalysts mercaptans lose hydrogen sulphide and are converted into thioethers. With activated carbon or alumina carrying cadmium or zinc sulphide, temperatures of about 300°C. are required.[106] At 150-210°C. and under 5 to 50 atmospheres, the sulphides of phosphorus or molybdenum may be employed as contact agents.[107] Before subjection to thermal treatment, substances which may act as catalyst poisons should be eliminated from mercaptans.[108] This may be accomplished by bringing the latter into contact with a solid adsorptive or polymerizing agent, e.g., activated charcoal, at 200-600°C.

Another procedure for the preparation of thioethers is that described by Lee.[109] Olefins, such as propene, butene-2, or pentene-2, are converted into the corresponding sulphuric acid esters and these in turn treated with a mercaptan. Thus, to an ester mixture comprising *ter*-amyl hydrogen sulphate, di-*ter*-amyl sulphate, and sulphuric acid (75 per cent concentration) is added ethyl mercaptan. The reactants are kept stirred until reaction is complete, overheating being carefully avoided. The oily layer, which separates, is removed, washed, neutralized, dried and distilled. The product is essentially *ter*-amyl ethyl sulphide. Klein[110] suggests utilization of the reaction between aromatic sulphonic acids and mercaptans. For example, 1,8-dilauryl thioether of anthraquinone can be made from disodium anthraquinone-1,8-disulphonate and lauryl mercaptan at a temperature of 130-160°C. and under a pressure of about 30 pounds per square inch.

The type of product obtained by combination of mercaptans and acetylene depends largely upon the catalyst employed.[111] In the presence of basic compounds vinyl thioethers are formed. Thus, when acetylene is passed into a mixture of phenyl mercaptan, *n*-butyl alcohol and potassium hydroxide (in an autoclave) until the pressure is 15 atmospheres and the reactants heated for 16 hours at 160°C., vinyl phenyl sulphide is obtained in a 91 per cent yield. If zinc acetate be added to the above-mentioned ingredients, then vinyl phenyl sulphide and *sym*-diphenyl ethylene sulphide ($C_6H_5SCH_2CH_2SC_6H_5$) are secured in 25 and 75 per cent yields, respectively. Cadmium salts may be used as catalysts in a similar manner.

Hydroxythioethers are prepared by the interaction of mercaptans with olefin oxides.[112] To illustrate, ethyl mercaptan and ethylene oxide give 2-hydroxydiethyl sulphide, and phenyl mercaptan and this oxide (in the presence of activated charcoal) unite to form phenyl-2-hydroxyethyl sulphide. At 90°C., propyl mercaptan and cyclohexene oxide yield propyl-2-hydroxycyclohexyl sulphide. Condensation of higher mercaptans, e.g., *n*-dodecyl mercaptan, and ethylene oxide (using sodium methoxide as catalyst) furnish compounds which are soluble in water and may be employed as scouring, dispersing, wetting and emulsifying agents.[113]

The addition of aromatic mercaptans to acetylene derivatives is described by Kohler and Potter.[114] As an example, 24.8 g. of thiocresol were added slowly to 20.4 g. of phenylacetylene, sufficient cooling being employed to prevent the reaction temperature from exceeding 100°C. The product, *p*-methyltolyl benzal sulphide ($CH_3C_6H_4SCH{=}CHC_6H_5$), exists in two isomeric forms; the one having the higher melting point (65°C.) separates on dilution of the reaction mixture with petroleum ether. After filtration and evaporation of the filtrate under reduced pressure, the other isomer (m.p. 44°C.) is obtained. The relative proportion of isomers depends upon the reaction temperature, higher temperatures favoring the formation of the low-melting isomer. The higher melting compound is slowly isomerized on distillation. Both isomers can be oxidized with hydrogen peroxide in acetic acid to give, successively, the corresponding sulphoxides and sulphones.

Photochemical Reactions of Mercaptans. Weiss and Fishgold[115] investigated the effects of radiation from a mercury arc on neutral or alkaline aqueous solutions of mercaptans. The primary reaction was considered as

$$RSH + h\nu \longrightarrow RS + H$$

Also in these solutions where a certain proportion of the anion RS^- is present, an electron transfer occurs

$$RS^-HOH + h\nu \longrightarrow RS + H + OH^-$$

followed by

$$2H \longrightarrow H_2 \quad \text{and} \quad 2RS \longrightarrow RS{-}SR$$

The quantum efficiency with respect to the development of hydrogen was always less than unity, indicating that reverse reactions were taking place. That is, hydrogen atoms and RS radicals were recombining and also disulphides were being reduced to mercaptans. Some splitting of mercaptans into hydrocarbons and sulphur was observed.

These investigators also report that many compounds possessing a —SH group react with fluorescent dyes in the dark. On irradiating with light which is absorbed by the dye this reaction (reduction action) is accelerated. Weiss and Fishgold believe that the strong quenching effect of such sulphur compounds on fluorescent dyes is represented in principle by the reactions given above, in which the activated dye replaces the quantum.

Interaction of Mercaptans with Aldehydes and Ketones. As previously mentioned, mercaptans combine with aldehydes and ketones to form mercaptals and mercaptoles, respectively. The products obtained from aromatic mercaptans and formaldehyde, however, depend upon the relative proportions of the two reactants.[116] Thus, *p*-thiocresol (2 moles) and formaldehyde (1 mole) dissolved in acetic acid and the solution saturated with hydrogen chloride yield the oily insoluble mercaptal,

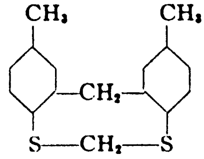
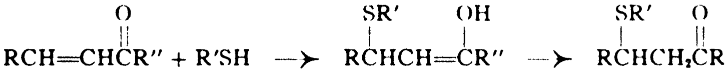
[116] W. H. Taylor, *J.A.C.S.*, 1935, **57**, 1065; *Chem. Abs.*, 1935, **29**, 5090; *Brit. Chem. Abs.* **A**, 1935, 970.

When a large excess of formaldehyde is employed, a crystalline material is obtained. It is suggested that possible condensation of the mercaptal with the aldehyde has occurred, resulting in a methylene bridge formation giving rise to a compound of the type



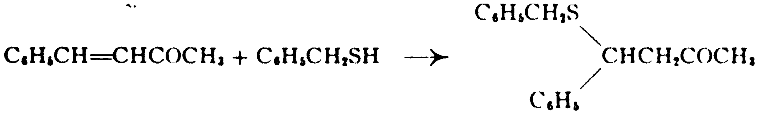
With unsubstituted aromatic mercaptans and formaldehyde (in acetic acid containing dissolved hydrogen chloride) either oily liquids (with the proper amount of aldehyde) or wax-like solids (with excess aldehyde) resulted. The waxy masses appeared to be mixtures of polymers. It was further noted that mercaptals from unsubstituted thiophenols and various other aldehydes yielded practically the same product on treatment with formaldehyde, thus indicating that the latter replaced the aldehyde residue originally present.

Mercaptans unite with α,β-unsaturated ketones to give β-ketosulphides.[117] Nicolet[118] points out that this reaction may be considered as a 1,4-addition to the conjugated series of double bonds, and can be represented as



$$RCH{=}CH\overset{\overset{O}{\|}}{C}R'' + R'SH \longrightarrow R\overset{\overset{SR'}{|}}{C}HCH{=}\overset{\overset{OH}{|}}{C}R'' \longrightarrow R\overset{\overset{SR'}{|}}{C}HCH_2\overset{\overset{O}{\|}}{C}R''$$

Furthermore, although alkaline catalysts (e.g., pyridine or sodium ethoxide) are often employed, these reactions in many instances are reversible and the initial products can be regenerated by heating the keto-sulphide with alkali. Later work[119] has shown that this condensation can take place in many cases without the aid of catalysts. For example, by gently heating a mixture of benzalacetone and benzyl mercaptan a good yield of phenyl-β-benzylmercaptopropione is obtained.



$$C_6H_5CH{=}CHCOCH_3 + C_6H_5CH_2SH \longrightarrow \begin{matrix} C_6H_5CH_2S \\ \diagdown \\ \quad CHCH_2COCH_3 \\ \diagup \\ C_6H_5 \end{matrix}$$

SWEETENING OF SOUR DISTILLATES

By sweetening of sour distillates commonly is meant the elimination of mercaptans, generally by converting them to disulphides (which, however, remain dissolved in the distillates) or by extraction with various liquid or solid media. The same purpose may be accomplished also by thermal treatment of petroleum fractions whereby mercaptans are changed to thioethers and hydrogen sulphide.

Probably the most widely used sweetening operation is the so-called "doctor sweetening" which consists essentially in agitating the sour distillate with aqueous sodium plumbite, whereby lead mercaptides soluble (for the most part) in oil are formed, and then recovering the lead as lead sulphide by the addition of sulphur. These reactions may be represented by

$$Na_2PbO_2 + 2RSH \longrightarrow 2NaOH + Pb(SR)_2$$
$$Pb(SR)_2 + S \longrightarrow PbS + RS-SR$$

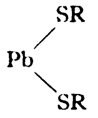
---

[117] For the preparation of a number of such compounds, see S. Ruhemann, *J.C.S.*, 1905, **87**, 461; *Chem. Zentr.*, 1905, 1, 1640.

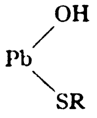
[118] B. H. Nicolet, *J.A.C.S.*, 1931, **53**, 3066; *Brit. Chem. Abs.* **A**, 1931, 1156; *Chem. Abs.*, 1931, **25**, 4850.

[119] B. H. Nicolet, *J.A.C.S.*, 1935, **57**, 1098; *Chem. Abs.*, 1935, **29**, 5090; *Brit. Chem. Abs.* **A**, 1935, 975.

Actually the reactions are not so simple as those indicated above since lead is known to form not only neutral but also basic mercaptides and these



neutral mercaptide



basic mercaptide

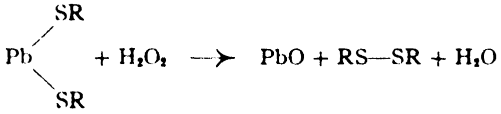
combine with sulphur to give various types of lead-sulphur compounds.[120]

In addition to lead oxide or aqueous sodium plumbite (doctor solution) other reagents have been used as sweetening agents, for example, sodium hydroxide, magnesium hydroxide (brucite), manganese dioxide, phosphorus pentoxide, hypochlorites and lead sulphide.

Perhaps the two greatest disadvantages connected with doctor and many other sweetening operations for gasolines are: (1) the resulting disulphides are soluble in the petroleum distillates thereby reducing the lead susceptibility,[121] and (2) the use of alkaline reagents often extracts phenols or other naturally occurring autoxidation inhibitors thus increasing any tendency to instability of the fuel, particularly those from cracked distillates, on storage.[122]

Use of Lead Compounds. In sweetening gasoline, Thacker[123] suggests that after agitation with doctor solution the latter be withdrawn and elemental sulphur in amount not to exceed 0.001-0.006 per cent of the gasoline be added. The liquid is then maintained in a quiescent state for 5-24 hours. Snyder[124] recommends after doctor treatment an addition of insufficient sulphur to completely precipitate lead sulphide but adequate to produce an oil of sweet odor. The oil may then be treated with clay or carbon to remove all color. Also it has been pointed out that the sulphur compounds may be removed from oils by treating the latter with doctor solution, and then passing the oil over a substance which will adsorb the lead-sulphur compounds.[125]

Instead of precipitating lead as the sulphide, decomposition of lead mercaptides by hydrogen peroxide to give lead oxide and disulphides is proposed.[126] The reaction involved in this instance may be represented as:



Another oxidizing agent which may be employed in a similar manner is potassium permanganate.[127]

---

[120] For a review of the reactions involved in the sweetening operation, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[121] The effect of various sweetening operations on the antiknock properties of gasolines is discussed by C. Wirth, III, and G. B. Murphy, *Oil and Gas J.*, 1936, **34** (38) 28; *J. Inst. Pet. Tech.*, 1936, **22**, 211A; *Chem. Abs.*, 1936, **30**, 3212.

[127] F. B. Behrens, U. S. P. 1,927,147, Sept. 19, 1933, to Universal Oil Products Co.; *Chem. Abs.*, 1933, **27**, 5961; *Brit. Chem. Abs.* B, 1934, 789.

Removal of mercaptans may be accomplished also by using mixtures of lead oxide, sodium silicate, and borax[128] or of lead oxide and calcium hydroxide.[129] Other procedures comprise treating the sour distillate with air[130] or sodium peroxide[131] in the presence of lead sulphide suspended in aqueous alkali. An alkaline solution containing lead sulphide in suspension has also been suggested.[132] Sweetening stabilized (depropanized) naphtha with doctor solution and then contacting unstabilized naphtha with the spent solution to secure regeneration of the latter and a mercaptan-free distillate is described by Endres.[133]

By-products from Spent Doctor Solution. Valentine and MacLean[134] report that 10,500 gallons of a typical spent doctor solution contained

Lead oxide	444 lbs.
Caustic soda	5050 lbs.
Sodium thiosulphate	8510 lbs.
Phenolates	8020 lbs.
Sodium chloride	130 lbs.
Sodium carbonate	240 lbs.
Sodium sulphate and sulphite	1600 lbs.

They suggest two methods for the recovery of these compounds. In the first, lead is precipitated as the sulphide, phenols are then removed and recovered by steam distillation, and the salts are obtained by evaporation of the liquid and fractional crystallization. In the second procedure, sulphur dioxide is passed into spent doctor until the lead is eliminated. Phenols are then separated. Afterwards, sulphur is added to the solution and on evaporation sodium chloride and sulphate are salted out while the sulphites are converted into thiosulphates. The latter are obtained by cooling the hot concentrated liquor.

Thiophenols are often found admixed with the phenolic bodies from spent doctor. These sulphur-containing compounds may be removed by passage of the phenol vapors over weathered lead sludge (from plumbite solution) at temperatures approximately 55°C. higher than their boiling point.[135]

It has been proposed also to weather lead sulphide sludge for 10-12 hours, whereby lead oxide and sulphur are produced.[136]

Use of Copper Compounds. Cupric salts, in the form of ammonio-cupric derivatives, are known to react with mercaptans to furnish oil-soluble cupric mercaptides. Treatment of sour distillates with metallic copper or copper compounds is said to result in mercaptide formation.[137] This may be accelerated if the oil contains dissolved ammonia, hydrogen chloride or sulphur dioxide. In some instances, however, reduction of the cupric salts by mercaptans occurs which results in the formation of cuprous mercaptides (sometimes oil-insoluble) and organic disulphides. This latter reaction (reduction of cupric salts) is utilized by Schulze and Buell[138] who employ either solutions of or solid supric salts.

On contacting sour gasoline with aqueous solutions of cupric chloride, two reactions take place ultimately bringing about reduction of the cupric salt and oxidation of mercaptans to disulphides. These can be represented as:

$$\begin{aligned} 4RSH + 2CuCl_2 &\longrightarrow RS{-}SR + 2RSCu + 4HCl \\ 2RSCu + 2CuCl_2 &\longrightarrow RS{-}SR + 4CuCl \end{aligned}$$

Hydrogen chloride remains dissolved in the aqueous layer. Cuprous chloride stays suspended in the water layer, or if the latter contains a sufficiently high concentration of chloride ion the cuprous salt is dissolved. Regeneration of the solution is effected by blowing with air.

$$4CuCl + 4HCl + O_2 \longrightarrow 4CuCl_2 + H_2O$$

In the other procedure, a solid absorbent, e.g., fuller's earth, is impregnated with the cupric salt and the sour distillate filtered through it. In this instance, continuous regeneration of the agent may be effected by dissolving a predetermined amount of air in the distillate.

The use of neutral aqueous solutions of cupric salts is described by Henderson and Cowles.[139] In this instance also the spent treating agent is activated by blowing with air or oxygen.

Use of Alkaline Agents. Treatment of sour oils with substantially anhydrous alkalies, such as sodium and potassium hydroxides,[140] results in sweetening and also desulphurization. Often a small proportion of elemental sulphur is added to assist in completing the reaction, whose course is probably indicated by:

$$2RSH + S + 2NaOH \longrightarrow RS{-}SR + Na_2S + 2H_2O$$

In addition to sodium sulphide, however, some sodium polysulphide and thiosulphate are also formed. Moser[141] suggests inhibiting the corrosive action of sulphur in oils sweetened in this manner by the addition of a small quantity of an unsaturated hydroaromatic, such as tetrahydronaphthalene or cyclohexene. In other instances, the proportions of free (or elemental) and mercaptan sulphur can be adjusted prior to the alkali treat so that the resulting product is non-corrosive.[142] The use of aqueous solutions containing sodium hydroxide and sodium polysulphide (as oxidizing agent) are described by Schulze and Chanel.[143] Stagner[144] employs caustic alkali dissolved in alcohol, particularly methanol.

Another method comprises mixing petroleum distillates with a solution of sulphur in a hydrocarbon oil and conducting the mixture through a bed of brucite.[145] In this manner acidity is neutralized and mercaptans are changed to disulphides.

Other Sweetening Agents. Hypochlorite solutions, either of the free acid or its salts, have been proposed as sweetening agents. Unless the concentration or alkalinity (in the case of salt solutions) is not carefully regulated, mercaptans in the oil may be oxidized not only to disulphides but also to sulphoxides, sulphones or sulphonic acids. Formation of sulphur chlorides may also take place. Best results are said to be obtained with reagents furnishing available chlorine in a highly dilute aqueous solution whose concentration is about 0.07 normal.[146] Catalysts, e.g., copper salts, may be added to such solutions.[147] When sulphur compounds having oxidizing properties are formed (during hypochlorite treatment) they may be reduced by the addition of mercaptans.[148] Alkyl sulphur chlorides are converted to disulphides by the action of alkali or alkaline earth sulphites, cyanides or stannites.[149]

Nisson[150] suggests a combination of doctor and hypochlorite sweetening. After agitating the sour distillate with aqueous sodium plumbite, insufficient sulphur to completely eliminate the lead as the sulphide is added. Following removal of the precipitate the oil is further treated with aqueous sodium or calcium hypochlorite. Pevere[151] recommends the use of aqueous alkaline solutions of phenol or aminophenol, and a mild oxidizing agent such as hydrogen or sodium peroxide. These peroxides may be employed also in acid solutions.[152]

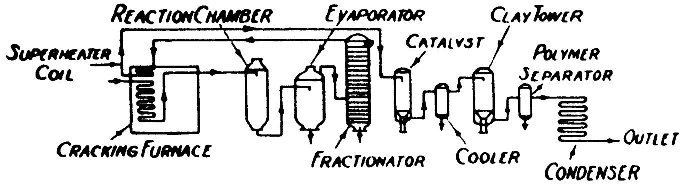

FIG. 126.—Flow Chart of Method for Removal of Mercaptans from Distillates by Conversion to Hydrogen Sulphide. (A. E. Buell and W. A. Schulze)

Passage of sour gasoline vapors over bauxite at 320-400°C. is reported to effect conversion of mercaptans to hydrogen sulphide.[153] For example, a sample of gasoline (produced by pressure cracking) with a sulphur content of 0.156 per cent (after removal of hydrogen sulphide) was conducted over bauxite at the above temperatures. The rate of flow was maintained at 6.1 barrels of gasoline per ton of bauxite. It was found that a sharp decrease in sulphur content was obtained, this reduction amounting to about 41.7 per cent. However, it was stated that the gasoline remained sweet to doctor solution until more than 500 barrels of gasoline per ton of bauxite had been desulphurized. The process is illustrated diagrammatically in Fig. 126. With cracked gasolines temperatures of 260-430°C. are used and a chromite ore as a catalyst.[154] Chromium-lead ores, such as vandite or descloizite, may be employed. The vapor-phase sweetening of gasoline with fullers' earth at 550-850°C. is described by Gray.[155] Also, it has been suggested that mercaptans in some cracked gasoline be converted into mercaptans of higher molecular weight.[156] The change was effected by passing the gasoline over active carbon, zinc sulphide and cadmium sulphide at temperatures between 250° and 350°C.

THIOETHERS

Sulphur compounds of this type have been isolated from the acid extract obtained in treating petroleum fractions with sulphuric acid or from distillates as insoluble double compounds with mercuric chloride.[157] The boiling points and molecular heats of vaporization of some of the lower boiling thioethers were determined by Thompson and Linnett.[158] See Table 108. Application of Trouton's law[159] to these data indicates that the sulphides are normal unassociated liquids.

TABLE 108.—*Boiling Points and Heats of Vaporization of Some Thioethers.*

Thioether	Boiling Point °C.	Heat of Vaporization
Dimethyl . .	37	6910 cal.
Methyl ethyl . . .	65	7250 cal.
Diethyl	91.4	8000 cal.

Probably the most general method for the preparation of aliphatic sulphides is the reaction of alkyl halides with sodium sulphide.[160] A modification of this is the action of alkyl halides on mercaptans, thus making possible the synthesis not only of thioethers containing alkyl radicals but also those having substituted radicals. For example, from decyl mercaptan and a polyglycerol chloride there is obtained a product which, in aqueous solutions, may be employed for washing wool containing suint.[161]

Another procedure, mentioned previously, for making thioethers is the thermal decomposition of mercaptans. Elbel[162] suggests reaction between a diazotized aromatic amine and an aliphatic mercaptan possessing at least six carbon atoms. If the amine has a sulphonic acid group then the resulting sulphide exhibits saponaceous properties.

Oxidation of sulphides, first to sulphoxides and then to sulphones appears to be characteristic. Many oxidizing agents may be employed for this purpose, as for example, selenium dioxide,[163] nitric acid, potassium permanganate or bichro-

mate, and hydrogen peroxide. Böeseken and Arrias[164] used peracetic acid with aromatic sulphides. They noted that the first reaction, formation of sulphoxides, was several hundred times as rapid as the latter, that is, conversion to sulphones. Furthermore, the velocity coefficient increased with increasing concentrations of the acid. Similar observations were made with *p*-bromophenyl thioether, though the rates of reaction with this compound were much less than for the diphenyl analogue.

DISULPHIDES

Although these compounds are known to exist in crude petroleum, or its distillates, their presence in refined products can be attributed also in a large measure as a result of the sweetening operation. This is particularly true of gasoline and kerosene fractions. As pointed out before, sweetening is primarily transformation of mercaptans to disulphides by mild oxidation and a number of methods have been previously described. As an example, a sour oil is subjected to the action of air in the presence of catalysts such as oxides of copper, lead, nickel, manganese or platinum.[165] Reaction can be controlled so that the hydrocarbons are unaffected.

Alkaline liquors containing dissolved mercaptides may serve as the raw material, and oxidation carried out at temperatures of about 100°C. and under a pressure of 80 pounds per square inch.[166] Separation of disulphides thus formed from the aqueous layer can be accomplished by extraction with a petroleum distillate, e.g., gas oil.[167]

Other procedures comprise vapor-phase oxidation of mercaptans at 225°C. using activated charcoal as the contact agent,[168] and the use of chloric acid (or its salts) in an aqueous medium for liquid-phase operations.[169] In the latter instance osmium tetroxide may be employed as a catalyst. Rider and Shelton[170] prepared benzoyl persulphide by mixing benzoyl chloride with aqueous sodium hydrogen sulphide, and oxidizing the product with air. Purification of the sulphide was accomplished by dissolving it in chloroform and then precipitating by the addition of alcohol.

Elbel and Kirstahler[171] reduced disulphides to the corresponding mercaptans by boiling with aqueous sodium hydrosulphide.

Although the presence of disulphides in refined gasolines is less objectionable than that of mercaptans from the standpoint of odor, nevertheless disulphides do exert a deleterious effect on the lead susceptibility or lead response of such fuels. For instance, Schulze and Buell[172] report addition of 1 cc. of lead tetraethyl to 1 gallon of a gasoline increased its octane number by 12.5, but that incorporation of 0.41 per cent by weight of sulphur as ethyl disulphide to the leaded fuel reduced this gain to 4. They also point out that for aliphatic sulphur compounds the larger the alkyl radical and the more branched its structure the greater is the decrease in lead susceptibility. With some gasolines, sweetening followed by distillation to 10 per cent bottoms results in a product of 4 octane numbers higher than that secured by the reverse procedure.[173]

POLYSULPHIDES

The presence of compounds of this type, as well as their formation during sweetening or acid refining operations, in petroleum distillates has been observed.[174] Generally these are high-boiling liquids, which in many instances may be concentrated by fractional distillation. Often they exhibit corrosive properties which render them undesirable constituents of petroleum products.

Diethyl trisulphide, $(C_2H_5)_2S_3$, may be obtained by heating diethyl sulphide and sulphur at 150°C.[175] Distillation of potassium ethyl sulphate and potassium sulphide yields a mixture of the alkyl di- and trisulphide, which may be transformed completely into the latter by treatment with sulphur. The trisulphide reacts with copper or mercury to give the corresponding metallic sulphide, and is oxidized by nitric acid to sulphuric and ethyl-sulphonic acids in the molecular ratio of 1:2.

Holmberg[176] reported that organic sulphides and disulphides (in alcohol) combine with sulphur in the presence of ammonia to form reddish-brown addition compounds. In the case of thioethers this reaction can be represented by

$$R_2S + xS + yNH_3 \longrightarrow R_2S_{x+1}\cdot yNH_3$$

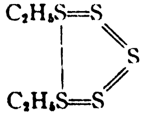
Some of these, such as the ethyl and *p*-tolyl disulphide derivatives, dissociate to furnish the tetrasulphide, sulphur and ammonia.

$$R_2S_x\cdot yNH_3 \longrightarrow R_2S_4 + S_{x-4} + yNH_3$$

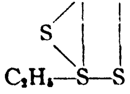
Other methods for the preparation of organic polysulphides include reaction of mercaptans with thionyl chloride,[177] thionylaniline[178] or sulphur chloride.[179]

$$\begin{aligned} 4RSH + SOCl_2 &\longrightarrow R_2S_2 + R_2S_3 + H_2O + 2HCl \\ 4RSH + C_6H_5NSO &\longrightarrow R_2S_2 + R_2S_3 + H_2O + C_6H_5NH_2 \\ 2RSH + S_2Cl_2 &\longrightarrow R_2S_4 + 2HCl \end{aligned}$$

Diethyl pentasulphide was made by heating sulphur chloride, sulphur and ethyl mercaptan (dissolved in carbon disulphide), a temperature of 150°C. giving the optimum yield.[180] Two isomers were obtained which boiled (under 26 mm. pressure) at 119°C. and 130°C., respectively. The structures suggested for these pentasulphides were



b.p. 119°C. (26 mm.)



b.p. 130°C. (26 mm.)

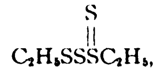
The high-boiling isomer is transformed into the low-boiling at temperatures above 200°C. The former also results from the action of sulphur on diethyl di-, tri- or tetrasulphide.[181] The physical properties of the polysulphides are given in Table 109.

TABLE 109.—*Physical Properties of Diethyl Polysulphides.*

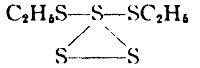
	Density	n_D^{15}	Boiling Point (at 26 mm.)
$(C_2H_5)_2S_3$	1.1140 (20°C.)	1.56899	85°C.
$(C_2H_5)_2S_4$	1.1253 (20°C.)	1.58436	109°C.
$(C_2H_5)_2S_5$ (I)	1.1687 (16°C.)	1.60269	119°C.
$(C_2H_5)_2S_5$ (II)	1.1620 (16°C.)	1.59517	130°C.

Later work by Baroni[182] on the determination of parachors[183] of various organic polysulphides (and also sulpho-selenides) indicates that di- and trisulphides possess straight chains, $C_2H_5SSSC_2H_5$, tetrasulphides a branched structure,



$$C_2H_5S\overset{\overset{\displaystyle S}{\|}}{S}SC_2H_5,$$

and pentasulphides a ring structure comprising three sulphur atoms.



A number of aliphatic mercaptans, thioethers and di- and tetrasulphides were prepared by Bezzi,[184] and some of the physical constants of these compounds determined. These values are given in Table 110.

TABLE 110.—*Physical Constants of Some Mercaptans, Thioethers and Di- and Tetrasulphides.*

Mercaptans, thioethers and disulphides were colorless liquids with disagreeable odors. Tetrasulphides were light yellow liquids. Attempts to deodorize these sulphur compounds with copper[185] at 200-250°C., also with mercury or magnesium, were unsuccessful. Devarda alloy,[186] on the other hand, effected complete decomposition.

[183] The panachor is calculated according to the formula $P = (M/D - d)\ \gamma^{1/4}$ in which M is the molecular weight, D and d are the densities of the liquid and vapor phases, respectively, and γ is the surface tension in dynes per square centimeter. S. Sugden, "The Parachor and Valency," Geo. Routledge & Sons, Ltd., London, **1930**.

[184] S. Bezzi, *Gazz. chim. ital.*, 1935, **65**, 693; *Chem. Abs.*, 1936, **30**, 2171.

The atomic refraction of sulphur in these different types of compounds varied considerably, ranging from 8.761 (in tetrasulphides) to 7.95. These values, Bezzi believed, excluded the possibility of all sulphur atoms being present as chains.

Measurements of the absolute viscosities and also the viscosities of dilute solution in ether, benzene and chloroform, of the sulphur derivatives were made by Bezzi.[187] The results indicated there was a simple relation between absolute viscosity and molecular weight and this was independent of the chemical constitution. Also the viscosities of chloroform and ether solutions, of different concentrations and at different temperatures, show that the various sulphur compounds behave normally and that the lengths of the molecules (with the same alkyl radicals) are equal in mono-, di- or tetrasulphides. According to Bezzi, organic polysulphides do not contain normal chains of sulphur but constitutions similar to those proposed for inorganic polysulphides,[188] viz., a coordinated union of the alkyl groups and other sulphur atoms around one sulphur atom.

Cyclic Sulphur Compounds

The occurrence of thiophene, and its homologues, in petroleum oils or in cracked distillates has been reported by a number of investigators.[189] These sulphur compounds are isolated, for the most part, as the corresponding mercuric chloride derivatives. In chemical properties they appear to resemble benzene more than aliphatic thioethers. Thiophene, for example, yields substituted compounds with halogens rather than addition products, and nitro derivatives and sulphonic acids with nitric and sulphuric acids, respectively.

The catalytic decomposition of thiophene, in sulphur-free gasoline (boiling 80° to 100°C.), was studied by Orlov and Broun.[190] The catalysts employed were (1) a mixture of nickel, cobalt, aluminum and magnesium oxides (42:3:5:1), (2) cobalt oxide and (3) molybdenum trioxide. In each case, prior to use, the catalyst was reduced so as to give it a pyrophoric character. Afterwards the vapors of the gasoline solution mixed with hydrogen were conducted over the contact agent at a temperature of 400°C. In this manner as much as 70 per cent of the sulphur (as thiophene) was eliminated, and of the residue 50-60 per cent was composed of elemental sulphur, mercaptans, disulphides and thioethers. A nickel oxide catalyst proved best, although it eventually became poisoned by sulphur. Also, it has been suggested that carbon monoxide will remove thiophene from toluene at 300°C.[191] Molybdenum trisulphide was employed as a catalyst. It was stated that when carbon monoxide was introduced at a pressure of 1000 pounds per square inch, the sulphur content was reduced from 0.85 to 0.05 per cent. At atmospheric pressure, the proportion of sulphur was said to be reduced from 0.60 to 0.32 per cent. The use of 91-93 per cent sulphuric acid together with olefinic hydrocarbons is recommended to recover thiophene from benzene.[192]

---

[185] This method was recommended by J. Finckh (*Ber.*, 1894, **27**, 1239; *J.C.S.*, 1894, **66** (1), 353, *Chem. Zentr.*, 1894, **2**, 28) for deodorization of amyl and ethyl thioethers.

[186] Devarda alloy is composed of 39 parts copper, 59 parts aluminum and 2 parts zinc. See H. Brunner and A. Rapin, *Schweiz. Wochschr.*, 1908, **46**, 455; *Chem. Abs.*, 1908, **2**, 3347; *J.C.S.*, 1908, **94** (1), 863; *Chem. Zentr.*, 1908, **2**, 676

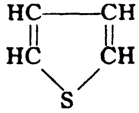
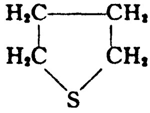
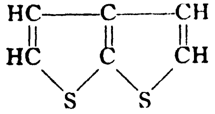
Closely allied to thiophene are thiophanes and thiophthenes. The relation between these various types is illustrated by the following formulas:



thiophene



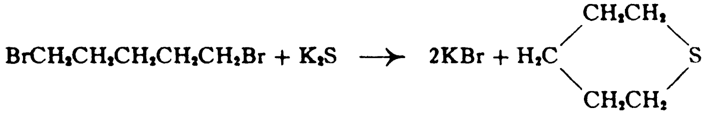
thiophane



thiophthene

Thiophanes, or hydrothiophenes, containing four or more carbon atoms have been isolated from petroleum oils or from the sulphuric acid extract (obtained in refining) as their addition products with mercuric chloride.[193] These liquid, sulphur compounds in many respects resemble thioethers in their chemical properties. They can be oxidized to sulphones, form sulphonium derivatives with alkyl halides, and addition products with metallic halides, e.g., chloroplatinates.

Hydrothiophenes may be prepared by the reaction of potassium sulphide with dihalogenated hydrocarbons.



In some instances, however, this method leads to the formation of polythiophanes, which are solids, of the types, $(C_8H_6S)_6$, $(C_5H_{10}S)_5$ and $(C_6H_{12}S)_4$.[194] Vigorous reduction of these polysulphides gives hydrogen sulphide and hydrocarbons, but no mercaptans. Dehydrogenation of thiophane in the presence of platinized charcoal and nickel sulphide on alumina has been reported.[195] The reaction was carried out in glass tubes 12 mm. in diameter and containing a catalyst bed 30 cm. in length. Temperatures of 315-400°C. were maintained when platinized charcoal was employed, and 350°C. with nickel sulphide. It was reported that hydrogen sulphide, olefins, paraffins, and some diolefins were obtained with both contact agents.[196]

Although the presence of thiophthenes has been suspected in coal-tar oil and shale oil, attempts to detect them have been unsuccessful. This is probably due to the fact that very little is known regarding the properties of such sulphur-containing bodies. With the object of learning more about its characteristics, Challenger and Harrison[197] prepared thiophthene by different methods and studied the materials so obtained.

One sample was made by heating a mixture of citric acid and phosphorus trisulphide.[198] The liquid product boiled at 220-221°C. and melted at 5.75-6.0°C. The structural formula assigned to it was

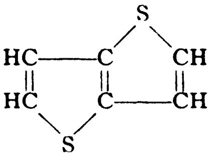
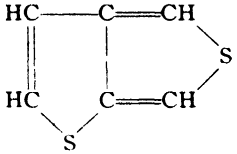
Another procedure employed was the reaction between sulphur and acetylene (in an atmosphere of carbon dioxide) at 440°C.[199] In this instance there were obtained carbon disulphide, thiophene, thionaphthene and two isomeric thiophthenes. Of the latter, one was a solid melting at 56°C., was called thiopheno-2',3'-3,2-thiophene, and was believed to have the formula



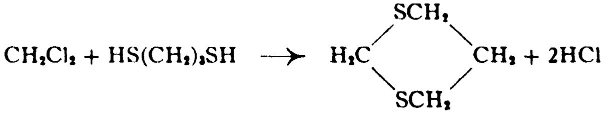
The other isomer was a liquid which boiled at 98°C. (13 mm.) and melted at 6.25-6.50°C. It probably possessed the structure indicated below, though this was not certain.



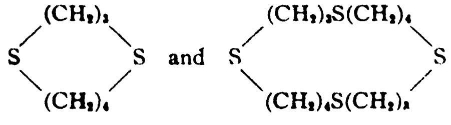
Such a compound could be designated as thiopheno-2',3'-3,4-thiophene.

All of the isomeric thiophthenes yielded characteristic addition products with picric or styphnic acid, mercurichloride derivatives, and mononitro compounds with nitric acid. With acetyl chloride and stannic chloride (as catalyst) they formed ketones which on reduction gave the corresponding ethyl thiophthene. The solid isomer (m.p. 56°C.) dissolved in alcohol and treated with sodium furnished an ethyl thiophene mercaptan, isolated as the mercury salt.

The formation of heterocyclic compounds containing two or more sulphur atoms has been observed by Meadow and Reid[200] by the action of dihalides on dimercaptans. For example, methylene chloride added to trimethylene mercaptan (in alcohol containing an equivalent quantity of sodium ethylate) yielded 1,3-dithiane.



Such reactions give rise not only to monomeric sulphur derivatives but also to polymers. Thus, from the same dimercaptan and tetramethylene bromide are secured a monomer and polymer (dimer) having the formulas,



---

captan, thiophane being an intermediate product, by hydrogenation at 350°C., using molybdenum trisulphide as a catalyst.

respectively. Depolymerization of the latter was accomplished by heating in the presence of hydrogen chloride.

UTILIZATION OF SULPHUR COMPOUNDS

Mention has been made of the possibility of converting hydrogen sulphide to sulphuric acid, and also of oxidizing aqueous alkali sulphides to thiosulphates. It has also been pointed out that elemental sulphur may be incorporated with some types of lubricants. When such incorporation is accompanied by the application of heat, the sulphur compounds resulting from the interaction of petroleum hydrocarbons and sulphur are said to be anti-oxidants.[201] The sulphur-containing bodies resulting from the hydrolysis of acid sludge (from the sulphuric acid refining of petroleum distillates) may be employed as denaturants for ethyl alcohol[202] or ethyl esters.[203]

Thioethers, and polysulphides, have been suggested as ingredients for fumigants[204] and, either alone or blended with other liquids, as solvents for rubber.[205] In the latter instance the solutions are said to be less viscous than those of the same concentration in carbon disulphide. Benzyl sulphide is reported to inhibit corrosion of aluminum by hydrochloric acid.[206] Various applications are suggested for the derivatives of thioethers. For example, dimethylethylsulphonium methylsulphate may be employed as a decolorizing agent for textiles.[207] Triethylsulphonium hydroxide may be used to loosen carbon deposits.[208] According to Kurtz,[209] dibutyl sulphone can be used for the extraction of naphthenic hydrocarbons from mineral oils.

Disulphides, such as ditolyl disulphide, mixed with thioethers or mercaptans, are said to furnish flotation agents for copper ores.[210] Taveau[211] finds that the ignition of Diesel fuels is accelerated by incorporation of 0.5 to 5 per cent of tetrasulphides.

Because of their greater chemical activity, mercaptans have found more applications probably than other types of sulphur compounds. The ease with which they are oxidized is well-known, and is possibly the basis for their use as oxidation inhibitors. About 1 per cent of a mixture of amyl mercaptan and dibutyl amine may be employed as a gum inhibitor for motor fuels derived from cracked distillates.[212] Other organic substances containing —SH groups may serve as

stabilizing agents for solutions of aromatic amino-hydroxy, polyhydroxy or polyamino compounds,[213] or for the prevention of peroxidase in the darkening of apples.[214]

Incorporation of mercaptans, which may be admixed with phenols, with alkali polysulphides and an emulsifying agent (naphthenic or sulphonic acids) yields insecticidal and fungicidal compositions.[215] Another procedure involves impregnating fuller's earth, acid-treated clay or silica gel with mercaptans and disulphides.[216]

The preparation of aralkyl thiocarbonates from the corresponding mercaptans is described by Hess.[217] For example, to 24.8 parts of benzyl mercaptan and 18.2 parts of carbon disulphide are added 10.8 parts of sodium hydroxide solution (74 per cent) and 12 parts of carbon disulphide. After stirring for one-half hour the mixture is allowed to evaporate to dryness at room temperature. The residual sodium salt of benzyltrithiocarbonate, $C_6H_5CH_2SCSSNa$, is a mass of yellow crystals which can be recrystallized from alcohol. Treatment of the salt with iodine or with alkyl halides gives the disulphide or alkyl esters, respectively. These various sulphur derivatives may be used as accelerators in the vulcanization of rubber or as flotation agents in the concentration of ores.

Mercaptans may serve as the starting material for the manufacture of sulphur bodies which possess detergent, wetting and emulsifying properties. The synthesis of such compounds is an application of the reaction between alkyl halides (or their derivatives) and alkali mercaptides. As an illustration, the sodium salt of dodecylmercaptoacetic acid (from the corresponding mercaptan and chloroacetic acid) is reported to possess soapy characteristics.[218] The chloro acid may be substituted by its esters.[218a] Thus, 23 parts of sodium are dissolved in 800 parts of absolute methanol and 202 parts of dodecylmercaptan then added. On incorporation of 122.5 parts of ethyl chloroacetate separation of sodium chloride begins, and reaction is completed by boiling the mixture for two hours. After removal of the precipitated salt, saponification of the product is effected by heating for one hour with alcoholic caustic soda The hot solution is neutralized with hydrochloric acid, and on cooling the sodium salt of dodecyl-thioglycolic acid is obtained as a white crystalline mass.

Organic sulphides resulting from the combination of mercaptans and esters of chlorinated carboxylic acids are suggested as softening agents for textiles.[219] An example of such is the thio compound made from dodecylchloroacetic ester and sodium phenylmercaptan. Sulphonation of aliphatic hydroxy-sulphides, from alkyl mercaptans and halohydrins, yields materials applicable as cleaning and emulsifying agents.[220]

According to Derby and Cunningham,[221] a flotation agent can be prepared in the following manner: Naphthalene is treated with phosphorus pentasulphide to furnish a naphthalenethiophosphoric anhydride. This in turn is reacted with phenol and the resulting product is combined with organic nitrogenous bases.

DESULPHURIZATION OF PETROLEUM DISTILLATES

Any attempt to completely survey refining operations applicable to various petroleum fractions is without the scope of this text. Indeed, limiting refining to the desulphurization of low-boiling distillates, particularly gasoline and kerosene, still embraces a wide field. However, as many developments in processes involving sulphur removal represent applications of the chemical reactions (just discussed) in which the various sulphur compounds take part, a brief summary of some of these methods is included.

Solvent extraction with concentrated sulphuric acid is well known. The disadvantages connected with the ordinary use of this agent, e.g., oxidation, polymerization of olefinic hydrocarbons, sulphation and sulphonation, have stimulated efforts towards the amelioration of such effects or the substitution of other agents. Davis and Hampton[222] suggest countercurrent treatment of distillates, the temperature being always less than —6°C. The employment of dilute sulphuric acid (35 to 80 per cent) which is subjected to electrolysis before being brought into contact with the petroleum fraction is another procedure.[223] An organic base, such as aniline or pyridine may be added to the sulphuric acid to reduce the activity of the latter.[224] Other extraction media which have been recommended are furfuraldehyde mixed with amylamine,[225] ethylenediamine,[226] and polyhydric alcohols or ethers therefrom.[227]

Solid treating agents such as metallic chlorides have been proposed. For example, aluminum chloride at 100-150°C. is reported to polymerize selectively the sulphur compounds in gasoline, after which separation of the reaction products is accomplished by filtration, decantation or settling.[228] It has been pointed out that this reagent is particularly effective with allyl, *sec*-butyl and benzyl sulphides.[229] *n*-Heptyl and ethyl sulphides are only slightly attacked. Other chlorides which may be employed are those of copper,[229a] titanium, iron, zinc or tin.[230] Another procedure comprises conducting gasoline vapors countercurrently to a molten stream of aluminum chloride mixed with zinc or cupric chloride.[231]

Desulphurization by alkalies has been accomplished, for example, by heating natural or cracked benzines, benzene or other motor fuels, under pressure with water solutions of sodium hydroxide.[232] According to Rosenstein,[233] sulphur compounds are removed by liquid ammonia and if alkali cyanides are added to the latter thiocyanates are obtained as by-products. Subjection of gasoline vapors, mixed with gaseous ammonia, to heated activated carbon[234] or to molten sodium or calcium[235] likewise has been proposed. Pines[236] effects removal of a large proportion of sulphur from cracked distillates with sodamide. For example, vapor-phase treatment of a cracked California gasoline with sodamide at 500-510°F. reduced the sulphur content from 0.56 to 0.23 per cent.

When vapors of sulphur-containing oils are brought into contact with aluminum sulphide at temperatures above 300°C. the sulphur bodies are decomposed to hydrocarbons and hydrogen sulphide.[237] Zinc sulphide, or complex compounds such as ferrous zinc sulphide, may be used in a similar manner.[238] Buell and Schulze[239] recommend bauxite at 600-750°F. as a sweetening and desulphurizing agent. The activity of this catalyst gradually decreases with use, this being more marked when cracked gasolines are treated than in the case of straight-run distillates. Reactivation may be accomplished by steaming followed by passing simultaneously air and steam at 775-800°F. through it. Other contact agents which have been proposed for the thermal decomposition of sulphur compounds are copper oxide,[240] ferric oxide,[241] silica gel[242] and adsorbent clays.[243]

Ellis[243a] points out that treatment of petroleum hydrocarbon vapors with a gaseous mixture consisting of hydrogen, methane, and carbon monoxide results in desulphurization. The proportion of hydrogen in the gas should be insufficient to produce saturated compounds. It is recommended that the operation be carried out at temperatures of 900° to 1020°F. and under a pressure of 50 atmospheres or higher. Catalysts which may be employed include the oxides of molybdenum or tungsten.

Morrell suggests vapor-phase treatment of petroleum distillates with ozone, using copper, ferric oxide or activated carbon as a catalyst.[244] Afterwards the distillate is subjected to the action of an aqueous salt solution (e.g., sodium bisulphate) containing sulphuric acid. Ozonization of gasoline in the liquid phase (at

—20°C.) followed by steam distillation is described by Kirsanov and Suslina.[245] The sulphur compounds are said to be converted partly into sulphuric acid and partly into non-volatile acidic and neutral bodies. Simultaneously with desulphurization there is a lowering of the iodine number and content of naphthenes, while the proportions of saturated and aromatic hydrocarbons increase. It is suggested that some gasolines contain sulphur derivatives of naphthenes and aromatics. The rate of desulphurization was not affected by water, lime, sulphuric acid or potassium dichromate.[246] Other oxidizing agents which have been proposed, particularly for cracked hydrocarbons, are aqueous solutions of an alkali pyrosulphate[247] or persulphate[248] and sulphuric acid, and oxides of nitrogen diluted with an inert gas such as carbon dioxide.[249] Hydrogen or sodium peroxide,[250] sodium persulphate mixed with alkali hydroxides or carbonates,[251] and per-acids, such as per-acetic or mono-persulphuric acid,[252] have been recommended.

The treatment of gasoline vapors with hypochlorous acid to secure a product of low sulphur and gum contents is described by Egloff.[253] Aqueous sodium hypochlorite exerts very little effect on thiophene though the free acid attacks it readily.[254] An effective solution of this acid can be prepared by adding acetic acid to a water solution of sodium hypochlorite until the p_H (glass electrode) is 3.9-4.0. This reagent appears partly to oxidize thiophene to sulphuric acid and partly to transform it to derivatives of much higher boiling points. According to Davis,[255] heterocyclic sulphur compounds are removed by subjecting the distillate to halogenation, in the presence of a catalyst, e.g., iron or aluminum, and afterwards heating with piperidine or its homologues.

Other desulphurizing agents which have been suggested are ferric sulphate,[256] metallic nitrides,[257] such as magnesium nitride, ferric nitrate,[258] and ammonium chloride vapors in the presence of zinc.[259] Maliyantz[260] reports that in many Russian crude oils the bacteria *Spirillum aestuari* produces a partial decomposition of sulphur compounds to hydrogen sulphide and sulphuric acid, and also some oxidation of the hydrocarbons. Such bacteria, however, do not act in an alkaline medium.

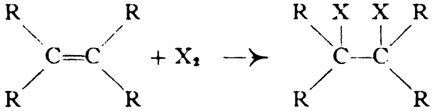
Chapter 20

Reactions of Olefins with Halogens. Olefin Dihalides and Their Derivatives

Olefin hydrocarbons, as a class, react easily with halogens, forming addition compounds.[1] This additive capacity distinguishes them from the paraffin hydrocarbons which are capable of forming substitution derivatives only. Direct combination of the unsaturated hydrocarbons to yield olefin dihalides or dihalogen derivatives of the corresponding paraffins may be represented as:



where X is a halogen atom and R a hydrogen atom or alkyl group.[2] Interaction between monolefins and halogens is most vigorous in the case of bromine, less so with chlorine, and even less so with iodine. It also appears that the rate of halogenation of the simple monolefins increases with increasing molecular weight up to a maximum and then decreases, though constitutional influences play an important role.[3] Further, though the addition of halogens to olefins occurs rapidly, substitution also takes place to some extent with the production of polyhalogen compounds. The power of unsaturated hydrocarbons of combining directly with bromine and iodine is the basis of a number of methods of estimating these hydrocarbons, some of which are discussed in Chapter 49.

In the naming of the addition products of unsaturated hydrocarbons, some questions concerning their designation may arise. For example, dichloroethylene ($ClHC=CHCl$) may be confused with ethylene dichloride ($ClH_2C—CH_2Cl$). The former is an unsaturated compound while the latter is completely saturated. The naming of the halogenated compounds by means of the unsaturated hydrocarbon from which they are derived serves to emphasize their origin. Although ethylene dichloride and 1,2-dichloroethane are the same material the name "ethylene dichloride" has been used to designate the compound made from ethylene by addition of chlorine, and "1,2-dichloroethane" to mean that made by substitution of chlorine for hydrogen atoms in ethane. Such distinctions are purely arbitrary, however.[4] As the series of hydrocarbons is ascended and the structure of the derivatives becomes more complex, the halogen compounds can only be designated as derivatives of the hydrocarbon, preceded by a prefix indicating the nature and number of the halogen atoms. Thus, in the case of butene-1, the compound which is formed on the addition of chlorine is named 1,2-dichlorobutane.

---

ETHYLENE DICHLORIDE (1,2-DICHLOROETHANE)

Ethylene dichloride, $ClCH_2CH_2Cl$, has been prepared, in general, by the addition of chlorine to ethylene. The reaction may be carried out in the vapor or liquid phase, in the presence of catalysts or by employing solvents. Temperatures above 25°C. cause the rate of reaction to be increased, and under these conditions it has been found difficult to limit the reaction to direct addition, since substitution nearly always occurs.[4a]

An explanation of the mechanism by which chlorine is added to ethylene has been offered by Stewart and Weidenbaum.[5] These investigators studied the photochlorination of gaseous ethylene in the absence and presence of gases which might accept chlorine. Also they investigated the effect of solvents which could interact with chlorine, such as ethylene dichloride and pentane. Photochlorination of ethylene was carried out by conducting a mixture of ethylene and chlorine, each at a pressure of 10 cm. of sulphuric acid, into a reaction flask. The latter was illuminated by light of approximately 4360 Å, furnished by a 500-watt tungsten lamp and was evacuated to 10^{-5} mm. of mercury before the reactants were introduced. The partial pressures of each gas were measured on a sulphuric acid manometer which also served to follow the reaction rate. It was reported that the addition proceeds at a rate proportional to the chlorine concentration at constant light intensity and independent of the ethylene concentration. Accordingly, a mechanism was proposed for the reaction,

$$\begin{array}{rcl}
Cl_2 + H\nu & \longrightarrow & Cl + Cl \\
Cl + Cl_2 & \longrightarrow & Cl_3 \\
Cl_3 + C_2H_4 & \longrightarrow & C_2H_4Cl_3 \\
C_2H_4Cl_3 & \longrightarrow & C_2H_4Cl_2 + Cl \\
C_2H_4Cl_3 + W^{a} & \longrightarrow & C_2H_4Cl_2 + \frac{1}{2}Cl_2
\end{array}$$

[a] W = wall of reaction vessel.

It was pointed out that when hydrogen was added to the above reactants and interaction allowed to take place in the absence of light, there was no detectable combination between hydrogen and chlorine. In the presence of light, even with a hydrogen-ethylene ratio of 9.64:1, only 10.7 per cent of the total chlorine which reacted combined with hydrogen. This would indicate a reactivity in favor of the ethylene of about 81-fold. It was suggested that this result be interpreted in terms of the difference in the heats of activation of the two reactions. Since the heat of activation of the photochemical hydrogen-chlorine reaction is 6000 calories, that for the addition of chlorine to ethylene photochemically would be less than 1400 calories.

In studying the effect of solvents upon the combination of chlorine and ethylene, the reaction was carried out at 0°C. by immersing the reaction flask in an ice bath. At the end of a definite length of time (30 or 60 seconds), the amount of chlorine which had been chemically combined was determined by adding potassium iodide and titrating the liberated iodine with sodium thiosulphate solution. The amount of hydrogen chloride produced, which was a measure of the amount of substitution, was obtained by titrating the contents of the flask with sodium hydroxide. When pentane was employed as a solvent, it was reported that from 35.5 to 73.6 per cent of the reacting chlorine produces hydrogen chloride. Further, if at a given initial chlorine concentration the initial ethylene concentration is increased, more substitution occurs. Conversely, a relative increase in the chlorine concentration decreases substitution. The latter was said to occur probably upon the pentane, as the use of ethylene dichloride as a solvent for the same reactants produced about 10 per cent substitution as a maximum.

[4a] Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[5] T. D. Stewart and B. Weidenbaum, *J.A.C.S.*, 1935, **57**, 2036; *Chem. Abs.*, 1936, **30**, 1303; *Brit. Chem. Abs.* **A**, 1936, 37.

The question was proposed as to whether the intermediate in this induced substitution of pentane is the same molecule as the intermediate in the photochemical chlorination of ethylene. A chlorine atom may be an intermediate in both the chain reaction of addition to ethylene and the chain reaction of substitution upon pentane, but, as in the case of the hydrogen-chlorine reaction, ethylene should be an efficient inhibitor for the pentane-chlorine interaction. Increasing ethylene should decrease, not increase, the substitution if chlorine atoms were responsible. Therefore, it was suggested that some derivative of ethylene is the intermediate in the substitution reaction. If chlorine atoms were competed for by both ethylene and chlorine, and if (of the two products) C_2H_4Cl promoted substitution and Cl_3 promoted addition, the data obtained could be qualitatively accounted for.

$$\begin{aligned}
Cl + Cl_2 &\longrightarrow Cl_3 \\
Cl + C_2H_4 &\longrightarrow C_2H_4Cl \\
C_2H_4 + Cl_3 &\longrightarrow C_2H_4Cl_3 \longrightarrow C_2H_4Cl_2 + Cl \\
C_2H_4Cl + Cl_2 &\longrightarrow C_2H_4Cl_3 \longrightarrow C_2H_4Cl_2 + Cl \\
C_2H_4Cl + C_5H_{12} &\longrightarrow C_2H_4 + C_5H_{11} + HCl \\
C_5H_{11} + Cl_2 &\longrightarrow C_5H_{11}Cl + Cl
\end{aligned}$$

The rates of chlorination of a number of gaseous olefins and the advantages offered by various types of apparatus have been reported.[6] It is stated that the combination of chlorine with different olefins proceeds with various velocities, the reactivity of the olefins increasing with the size of the molecule. Chlorine, if present in excess, combines primarily with the propenes and butenes rather than with ethylene, when the gases from the pyrolysis of petroleum are treated. The velocity of the chlorine as it enters the reaction zone is said to affect the yield, a high velocity favoring the production of dichlorides of all olefins present. The use of a solvent for the gaseous hydrocarbons brings about the formation of polychlorides. A lowering of the process temperature is suggested to inhibit substitution, although even at −10°C., polychlorides to the extent of 12 to 15 per cent are obtained. Combination of the reactants in the vapor phase in metallic apparatus is recommended to lower the proportion of higher chlorine derivatives. When the reaction temperature is in the range 40-50°C. and the ratio of chlorine to olefin is 1:1 by volume, from 90 to 95 per cent of the theoretical yield of dichlorides is said to be secured. Of the two types of metallic apparatus investigated, copper and iron, the former is advocated as more efficient. When an iron reaction chamber is employed, the product is stated to have a black color because of the ferrous and ferric salts which are formed. The presence of methane, hydrogen and carbon monoxide in cracking gas apparently does not interfere with the chlorination of the olefin portion, since the former gases are reported to be unaffected by the halogen.[7] Also, it was confirmed that the velocity of the chlorination of propene is so much greater than that of ethylene that a complete separation of the two dichlorides is possible. For this purpose, a method of fractional halogenation has been proposed.[8] The reaction unit consists of two iron chambers packed with iron turnings and connected by means of a tube. Cracking gas is fed into one chamber from the top and chlorine into both from the bottom. Reaction takes place in the first chamber, resulting in the chlorination of the homologues of ethylene which separate as liquids and are removed from the bottom. Ethylene, which is substantially unaffected, is then conducted into the second chamber where it is chlorinated. The temperature of the entire reaction zone is maintained between 70 and 120°C. and the yield of ethylene dichloride is reported to be 90 per cent of theoretical.

[8] A. F. Dobryanskii, R. A. Gutner and M. K. Shchigel'skaya, *Trans. State Inst. Applied Chem.* (*U.S.S.R.*), 1935, **24**, 21; *Chem. Abs.*, 1935, **29**, 7271; *Brit. Chem. Abs.* B, 1936, 1032.

A similar apparatus has been suggested for a liquid phase addition of chlorine to ethylene.[9] Combination was effected at 18-24°C. by conducting ethylene and chlorine in equimolecular proportions into a solvent consisting of ethylene dichloride. Or the reactants are passed into an iron tube filled with shavings of the same metal wet with ethylene dichloride. Employment of the latter substance is said to lower the amount of kerosene required for scrubbing the reaction products and to increase the amount of dihalide secured. A mixture of trichloro- and tetrachloropropanes and butanes has also been advocated as a solvent vehicle for the above reactants.[10] In this case, the solvent vehicle is conducted into the reaction chamber near the top while the ethylene and chlorine enter near the bottom. The temperature is maintained at 5°C. and the pressure at 1 atmosphere. As soon as the olefin and halogen are dissolved the liquid mixture is removed and afterwards washed, dried and fractionated. In the last step the solvent is separated and may be employed again. This is illustrated diagrammatically in Fig. 127. The yield of ethylene dichloride is reported to be between 68 and 76 per cent of the theoretical.

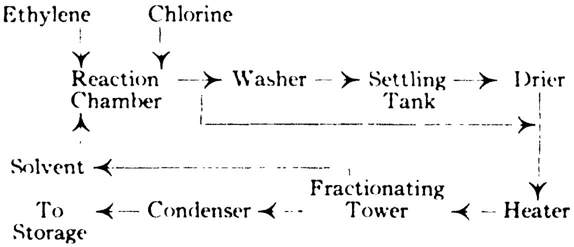

Fig. 127. Flow Sheet for Chlorination of Ethylene. (M. Berliner)

Contact agents are utilized to increase the speed of chlorination of ethylene in the vapor and liquid phases. Reynhart[11] points out that an ethylene cut, obtained from the low temperature fractionation of coke oven gas and containing 12.4 per cent of the above olefin, may be forced together with chlorine, at the rate of 1800 and 200 liters per hour, respectively through a "wetting" zone and then through a heater containing a promoter. The latter was secured by evaporating an aqueous solution of potassium ferrocyanide, aluminum chloride and ferric chloride. The temperature at the intake to the heater is 15°C., that of one-third and two-thirds of the length is 80°C. and 135°C., respectively. Upon issuing from the reaction chamber, the products were cooled to —5°C. to effect separation of the dihalides from the permanent gases. A yield of 90 per cent of the theoretical amount of ethylene dichloride was said to be gotten. In another process, catalysts are incorporated in solvents.[12] Among the former are included the chlorides of antimony, bismuth, iodine, phosphorus, sulphur, tin and manganese, and the solvent is tri- or pentachloroethane. Chlorine and gaseous olefin are led into the liquid solvent at 20°C. and 1 atmosphere pressure.

PROPERTIES AND USES OF ETHYLENE DICHLORIDE

Ethylene dichloride is a heavy, colorless liquid with a chloroform-like odor. It boils at 83.5°C. at 760 mm., freezes at —36°C., has d_4^{20} 1.2569, is soluble in water to the extent of 0.87 g. per 100 cc. of water at 20°C., and has a vapor pressure of 78 mm. of mercury at 20°C. In the presence of oxygen and ultraviolet light of short wave length, it is said to be converted into chloroacetic acid.[12a]

Its toxicity has been studied and compared with that of certain other organic compounds.[13] For single exposures over a period of an hour or more the poisonous effect of ethylene dichloride is reported to be of about the same order as that of benzene, carbon tetrachloride or chloroform. For periods of less than an hour it is stated to be less toxic than these compounds. A comparison with gasoline is made but since gasoline, as a commodity, may vary greatly in composition within those limits imposed by volatility and other requirements the original publication as well perhaps as the investigators themselves should be consulted for any needed data.

The odor of the dichloride vapor is distinct and noticeable in relatively safe proportions. Also, it is reported to produce marked symptoms of dizziness in concentrations that will not cause permanent injury. Since the data were obtained from a study of single exposures, no interpretation was drawn applying to the possible effects of repeated exposure. It was indicated, however, that repeated exposure would not cause a chronic type of poisoning of a nature other than the logical expectation of a possible accumulation of poisonous effects where the daily exposure is sufficient to cause the latter.

Solvent Properties. As a solvent, ethylene dichloride is said to possess many desirable characteristics, for example, high solvent power, low inflammability and availability in large quantities.[14] In the separation of mineral oils from paraffin wax, it has been suggested that the dichloride be employed alone[15] or admixed with *o*-dichlorobenzene and propene dichloride,[16] dipropyl ether,[17] methanol[18] or acetone.[19] At low temperatures (—10 to —25°C.) the dichloride or one of the compositions mentioned above is reported to dissolve the oil completely and almost none of the wax. On the other hand, it has been pointed out that ethylene dichloride is not applicable for the dewaxing of highly viscous oils.[20] The reasons advanced for this statement are the relative insolubility in ethylene dichloride of oils which have a relatively large proportion of solid paraffin present, and the selective properties of the solvent. By the second assertion is meant that some of the higher liquid hydrocarbons are relatively insoluble in ethylene dichloride and are transferred in part to the wax portion, so that the yield of dewaxed oil is lowered. The solvent properties of ethylene dichloride have been utilized in other preparations. For example, it may be employed to purify explosive substances. In one procedure the separation of di- and trinitrotoluene is brought about by dissolving a mixture of the two in 85 per cent of carbon tetrachloride and 15 per cent of ethylene dichloride. The solution is then cooled to recrystallize the trinitrotoluene, which has a higher melting point than the derivative containing two nitro groups.[21] Tetryl, or 2,4,6-trinitrophenyl methyl nitramine, may be purified by dissolving it in 1.7 times its weight of ethylene dichloride at 80°C. Upon cooling the solution to 20°C., the tetryl is said to be recrystallized.[22] Hard greases which are to be used in hot bearings are softened to some extent by the addition of a small proportion of ethylene dichloride [23] and then applied from a mechanical lubricating system. When it has been placed in the bearing the dichloride evaporates in the course of time, leaving a grease of the original consistency. An interesting use of the solvent properties of ethylene dichloride is for the extraction of white zein[24] from yellow corn. According to Mason and Palmer[25] yellow zein may be dissolved in hot 95 per cent ethanol. The addition of ethylene dichloride to this solution will effect the dissolving, in the dihalide, of any fat or pigment which is present. The decolorized zein may then be precipitated from the alcohol by incorporating acetone or ether in the latter. The last traces of color are removed from the zein by scrubbing it with ethylene dichloride. A mixture of acetic acid and the dichloride is reported to comprise a suspending vehicle for cellulose which is to be acetylated.[26] The suspension is heated and acetic anhydride incorporated, together with a small proportion of sulphuric acid which serves as a catalyst. A mixture of 80 per cent of chloroform, 16 per cent of ethylene dichloride and 4 per cent of ethanol is suggested as a solvent for water-proofing compositions.[27] The latter consists of 3.8 per cent of cellulose acetate and 11.5 per cent of hydrogenated rubber, which are incorporated in 84.7 per cent of solvent and applied to the cloth with a doctor knife. Also, it is said to be an efficient solvent for heliotropin (benzaldehyde-3,4-methylene ether) when the latter is to be converted to pyrocatechualdehyde (3,4-dihydroxybenzaldehyde).[28] The solvent properties of the dichloride have been utilized in the preparation of liquid insecticides containing rotenone.[29]

The conversion of ethylene dichloride to ethylene glycol, by hydrolysis with aqueous sodium carbonate, or to glycol diacetate, by heating with an anhydrous salt of acetic acid, is discussed in Chapter 22. When heated with caustic alkalies ethylene dichloride loses first one molecule of hydrogen chloride to yield vinyl chloride.

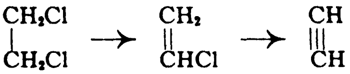
The properties and uses of this latter compound are mentioned in Chapter 28. Further treatment with caustic alkalies eventually yields acetylene, thus:

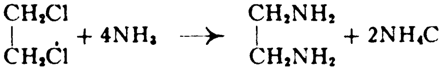


$$\begin{matrix} CH_2Cl \\ | \\ CH_2Cl \end{matrix} \rightarrow \begin{matrix} CH_2 \\ \| \\ CHCl \end{matrix} \rightarrow \begin{matrix} CH \\ ||| \\ CH \end{matrix}$$

A similar series of changes occurs when ethylene dichloride is subjected to pyrolysis at 600°C. in an atmosphere of nitrogen. Vinyl chloride and hydrogen chloride are produced (this reaction is probably reversible at lower temperatures), while at still higher temperatures acetylene is produced.[30]

Reaction of Ethylene Dichloride with Ammonia

Ethylenediamine may be produced from ethylene dichloride by interaction with ammonia, according to the equation



$$\begin{matrix} CH_2Cl \\ | \\ CH_2Cl \end{matrix} + 4NH_3 \rightarrow \begin{matrix} CH_2NH_2 \\ | \\ CH_2NH_2 \end{matrix} + 2NH_4Cl$$

Bersworth[31] suggests that liquid ammonia be heated in an autoclave to 150°C. to vaporize it and to generate a high pressure. Ethylene dichloride is then forced into the hot, compressed ammonia vapor, forming ethylenediamine hydrogen chloride (See Fig. 128). To recover the free diamine, the products are treated with caustic soda at 100°C. and conducted to an expansion chamber where the temperature is maintained at 130°C., which is above the boiling point of ethylenediamine (117°C.). The diamine vapors and unreacted ammonia are then led to a dehydrating column, where the diamine is dried and condensed. The unreacted ammonia may be recycled. In another procedure 500 g. of the dichloride, 1800 cc. of concentrated ammonium hydroxide, and 400 g. of cuprous chloride are placed in an autoclave and subjected to a temperature of 95°C. and a pressure of 150-300 lbs. per sq. in. for a period of 2 hours.[32] The copper salt is present in the reaction chamber to form a complex salt with the ethylenediamine produced. At the end of the heating period, sodium hydroxide is incorporated in the products, and the mixture is distilled. The portion boiling at 117°C. at 760 mm. is retained. It is reported that the yield of ethylenediamine is from 60 to 82 per cent of the theoretical. Other compounds which have been employed to form addition products with ethylenediamine include zinc chloride and zinc oxide.[33] To separate the diamine from its salts, it has been recommended that the latter be dissolved in liquid ammonia and then admixed with carbon dioxide.[34] In this manner the carbamate of ethylenediamine is said to be precipitated, and may be decomposed by heating with water. Mnookin[35] suggests that ethylene dichloride be treated with water and ammonia and a small proportion of ethanol to furnish ethylenediamine. The water is stated to act as a hydrolyzing agent, forming an intermediate with the dihalide with which the ammonia interacts. For example, 200 cc. of ethylene chloride, 340 cc. of concentrated ammonium hydroxide and 1600 cc. of water are heated at 140-150°C. and 150 lbs. per sq. in. for 0.5 hour to yield 40 per cent of the theoretical amount of aqueous ethylenediamine. To secure the anhydrous diamine, Bailar[36] recommended that zinc oxalate be mixed with an equivalent weight of the hydrate and the resulting compound dissolved in boiling water. On cooling the solution to 20°C. a complex crystalline salt with the formula $[ZnC_2H_4(NH_2)_2]C_2O_4$ separates. The latter is dried and heated to 200°C. under reduced pressure. At this temperature anhydrous ethylenediamine is liberated and condenses to a colorless liquid which boils between 116 and 117°C. and has d_4^{17} 0.907.

Ethylenediamine has been advocated as a softening medium for the hydrolysis of cellulose acetate yarn.[37] The latter are hydrolyzed non-uniformly along their length and stretched in the presence of the diamine. In this manner hydrolysis of the parts which were not affected in the first step is said to be accomplished. Also it has been pointed out that the addition of 0.5 per cent of ethylenediamine to motor fuel will increase the antiknock properties of the latter.[38]

REACTION OF ETHYLENE DICHLORIDE WITH SULPHIDES

The reaction between ethylene dichloride and alkaline earth sulphides leads to the formation of plastic materials. For example, the dichloride may be reacted with calcium or sodium sulphide in water in the presence of magnesium hydroxide to form a latex-like dispersion of a plastic which coagulates upon acidification of the mixture. The sulphide plastics thus formed are reported to be applicable as dielectrics.[39] Ethylene dichloride will interact with polysulphides, such as sodium polysulphide, in the presence of egg-albumin and magnesium hydroxide.[40] The latter substances are employed as protective colloids for the formation of the ethylene polysulphide. In one case, 250 g. of sodium polysulphide are incorporated with 1 g. of egg-albumin, 15 g. of magnesium chloride and 6 g. of sodium hydroxide in 125 cc. of water. The mixture is then heated to 100-110°F. (38-43°C.) under a reflux condenser and ethylene dichloride added slowly. At the end of 1.5 hours the temperature is raised to 190-195°F. (88-90°C.) for a few minutes. The water-soluble products are removed by extraction with water and the ethylene polysulphide coagulated by further addition of alkali. The olefin polysulphide obtained is said to be useful in molding operations. The addition of a small proportion (0.01-1 per cent) of dibutylamine, triethanolamine and monoethanolamine to ethylene dichloride and sodium polysulphide in carbon disulphide solution has been advocated.[41] The product obtained is stated to have many properties which resemble those of natural rubber. Certain of the reactions and properties of the ethylene polysulphides have been pointed out by Patrick.[42] When the polysulphide is heated with caustic soda at 80-90°C. ethylene disulphide is said to be formed. However, the polysulphide is stated to be unaffected by boiling acetone or by sublimation under a high vacuum. Ethylene disulphide is reported to be a thermoplastic powder[43] with no definite melting point and to be unaffected by organic solvents, including carbon disulphide.

OTHER REACTIONS AND USES OF ETHYLENE DICHLORIDE

Ethylene dichloride combines with salts of aliphatic acids to form esters from which ethylene glycol may be obtained. Coleman and Moore[44] report that the diacetic ester of ethylene glycol is furnished by the interaction of ethylene dichloride and sodium acetate in the presence of a catalyst consisting of pyridine. When sodium stearate is employed in place of sodium acetate, the product is ethylene glycol distearate.[45] This latter compound, when added to a dewaxed mineral oil in the proportion of 0.1 to 1 g. of ester per 100 cc. of oil, is said to lower the pour point of the oil about 10°F.

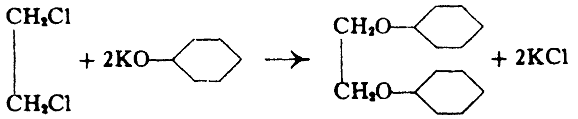
Potassium phenolate will interact with ethylene chloride to form diphenyl ethers. In 60 cc. of water are dissolved 0.2 mole of phenol, 0.2 mole of potassium hydroxide and 25 g. of ethylene chloride. The mixture is heated under a reflux condenser for 48 hours, cooled, filtered, and the potassium chloride washed out with water. The ether so obtained is said to constitute 75-80 per cent of the theoretical amount.[46]



Also, dinaphthyl ethers may be prepared by combining the metallic salt of a naphthol with ethylene halide. For example, ethylene glycol di-β-naphthyl ether is reported to be secured by heating together (in water) sodium β-naphtholate and ethylene chloride.[47] In this instance 60 g. of caustic soda, 576 g. of β-naphthol and 198 g. of ethylene dichloride were incorporated in 600 cc. of water at 20°C. The mixture was then heated in an autoclave at 120°C. for 8 hours. At the end of this period the products were made alkaline with sodium hydroxide, and the precipitated ethylene glycol di-β-naphthyl ether, which is insoluble in water, filtered from the remaining substances. A yield of 350 g. of the dinaphthyl ether was said to be obtained.

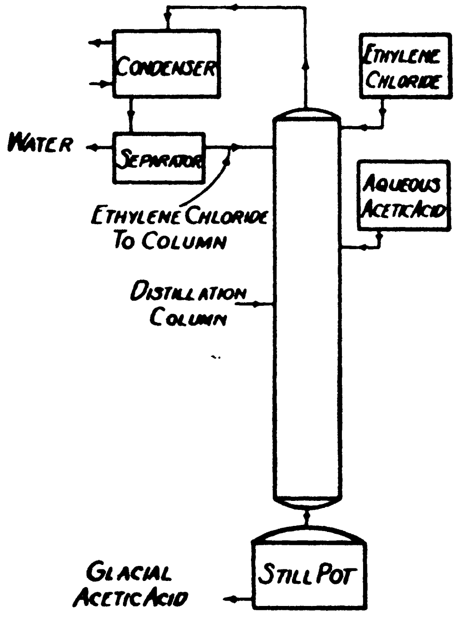


Fig. 129.
Use of Ethylene in Dehydration of Aqueous Acetic Acid. (D. F. Othmer)

The ability of ethylene dichloride to form azeotropic mixtures with water is utilized in dehydrating aqueous acids. Othmer[48] suggests the dichloride to remove the water from aqueous acetic acid. The apparatus consists of a unitary column with fractionating plates. The chloride is admitted at the top of the column and the aqueous acetic acid near the middle (see Fig. 129). In this manner an azeotropic mixture of water and the dichloride is said to be distilled, leaving anhydrous acetic acid in the residue. Aqueous solutions of propionic acid may also be distilled with ethylene chloride to bring about dehydration of the former.[49]

[46] A. C. Cope, *J.A.C.S.*, 1935, 57, 572; *Brit. Chem. Abs.* A, 1935, 614; *Chem. Abs.*, 1935, 29, 2947.

[47] M. A. Dahlen, C. K. Black and W. L. Foohey, U. S. P. 1,979,144, Oct. 29, 1935, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1935, 29, 177.

In the interaction between butyl alcohol and phthalic anhydride to produce butyl phthalate, ethylene dichloride may be incorporated in the reaction zone.[50] The purpose of this addition is to form an azeotropic mixture of ethylene dichloride and the water formed by the reaction. This mixture may be distilled off during the course of the interaction. In one instance, 300 g. of butyl alcohol, 200 g. of phthalic anhydride and 125 g. of ethylene dichloride were placed in a still together with 0.6 g. of sulphuric acid, which acts as a promoter for the esterification. The reactants were heated (under reflux) at 120°C. for 30 minutes, during which time a binary mixture of water and ethylene dichloride was said to leave the top of the columns at 71-72°C. Butyl phthalate was reported to be secured in 96 per cent yield.

A motor fuel containing triethylmethane and trimethylmethane is said to be obtained by conducting a gaseous mixture of acetyl chloride, ethylene dichloride and hydrogen over a contact agent. The latter consists of iron and nickel, and the reaction temperature is in the range 250-300°C.[51]

Also, it has been reported that chlorine and ethylene dichloride, in the vapor phase at 20°C., give hexachloroethane.[52] When the two reactants unite in the liquid phase in the presence of hydrogen chloride, the compound which is formed is trichloroethane.

ETHYLENE DIBROMIDE

The thermal combination of ethylene and bromine has been studied to determine the nature of the mechanism. It was found that the gaseous reaction at 20°C. is a surface phenomenon[53] which appeared to take place by the simple addition of bromine to the double bond.[54] The order[55] of the reaction was reported to be either second, first or zero, depending on the glass surface. For a given glass surface, either lowering the temperature or increasing the pressure of the reactants lowered the order of the reaction. The presence of water vapor served to accelerate the reaction, but baking the glass before reaction removed this influence. Therefore, it has been suggested that bromine is hydrated at the surface of the glass, and that the ethylene reacts with the bromine hydrate.

It has been pointed out that ethylene will unite with bromine in the dark at temperatures in the range 0-15°C.[56] The rate of formation of ethylene dibromide under these conditions is said to be proportional to the bromine concentration and inversely proportional to the ethylene bromide concentration. This may be expressed by the equation,

[55] A first order reaction is one in which the rate of decomposition of the original reactant at any time is proportional to its concentration at that time. In a second order reaction, with one reactant, the rate is proportional to the square of its concentration, and with two reactants, the rate is proportional to the product of their concentrations. A reaction of zero order is one in which the rate of reaction is independent of the concentrations of the reacting substances.

A mechanism has been proposed by Ogg[57] for the addition of bromine to an ethylenic linkage, when interaction is effected in the dark, at temperatures between 0° and 20°C. and in aqueous solution. Combination is stated to take place in two stages.

$$Br^- + RCH{=}CHR \longrightarrow RCHBr{-}C^-HR$$
$$RCHBr{-}C^-HR + Br{-}Br \longrightarrow RCHBr{-}CBrHR + Br^-$$

where R represents an alkyl group or a hydrogen atom. That is, the addition is catalyzed by a halide ion, and the intermediate is a carbanion. The latter is reported to have a stable configuration, and hence stereochemically[58] different products should result from *cis* and *trans* isomers. Further explanation is stated to be afforded of the generally observed *trans* addition of halogens to ethylenic linkages. Thus, the first reaction above is regarded as a substitution of the halide ion with one of the electron pair bonds of the ethylenic linkage. This stage is said to be attended by optical inversion[59] of the intermediate carbanion to the *trans* form. The carbanion thus has a *trans* configuration, and since no configuration change occurs in the second stage of the addition, the final product, it is pointed out, should be *trans*.

[58] These products rotate the plane of polarized light in opposite directions.

The effect of catalysts upon the rate of addition of bromine to ethylene has been investigated.[60] The union of bromine and ethylene was accomplished by mixing solutions of these reagents, both in dichloromethane at 18°C., in the dark. Hydrogen bromide was employed as catalyst in some of the experiments. The interaction was reported to be autocatalyzed when no hydrogen bromide is present. The course of the reaction was followed by withdrawing samples at definite intervals and placing them in a solution of potassium iodide. Unreacted bromine replaced the iodine, which was then determined by titration with sodium thiosulphate. A comparison of the results obtained with and without catalysts is shown in Table 111.

(see Fig. 131). In this manner the formation of a high yield of ethylene bromide is said to be facilitated. Bromine which is in excess may be separated from the products and returned to the reaction zone.

It is interesting to note that ethylene dibromide has been manufactured with bromine extracted from sea water.[62] The latter is acidified with sulphuric acid until a pH of 3.5 has been reached. Chlorine is then added to the water to liberate bromine. To extract the bromine, a current of air is forced through the sea water. All bromine blown out of the water is afterwards absorbed in aqueous sodium carbonate, forming a mixture of sodium bromide and sodium bromate. The mixture is then acidified with sulphuric acid to liberate bromine. The latter, after being extracted, is liquefied and mixed with ethylene at temperatures between 0° and 20°C. A yield of 95 per cent of the theoretical amount of dibromide is reported to be secured.

FIG. 132.—Flow Sheet for Making Ethylene Dibromide with Bromine Extracted from Sea Water.

REACTIONS OF ETHYLENE DIBROMIDE

The loss of one molecule of hydrogen bromide from ethylene dibromide leads to vinyl bromide, $CH_2{=}CHBr$. To accomplish this change it has been suggested that the products of the interaction between bromine and ethylene be heated above the boiling point of the dibromide (131.5°C.) and conducted into an alcohol solution of potassium hydroxide. The resulting vinyl bromide, which boils at 15.8°C., may be distilled from the products.[63]

[62] L. C. Stewart, *Ind. Eng. Chem.*, 1934, **26**, 361; *Brit. Chem. Abs.* **B**, 1934, 497; *Chem. Abs.*, 1934, **28**, 3189.

[63] French P. 751,970, 1933, to La soc. anon. des ateliers de constructions mécaniques Escher Wyss; *Chem. Abs.*, 1934, **28**, 783.

The preparation of diaryl ethers of ethylene glycol from ethylene dibromide has been described.[64] For example, ethylene glycol diphenyl ether is said to be furnished by the reaction between ethylene dibromide and potassium phenolate. A mixture of 0.2 mole of phenol and 0.2 mole of potassium hydroxide was dissolved in ethanol and 25 g. of ethylene bromide incorporated. The solution was then heated under a reflux condenser for 2 hours. On cooling and filtering, crystals of ethylene glycol diphenyl ether and potassium bromide were said to be furnished. The latter compound was removed by taking advantage of its relative solubility in water as compared to the ether. The yield of ether was reported to be rather low, possibly in consequence of the formation of vinyl bromide from ethylene dibromide and the alcoholic potassium hydroxide which were employed.

Ethylene dibromide and arsenious oxide will unite to produce a number of compounds the nature of which depends upon the reaction conditions. Backer and Bolt[65] point out that combination of dibromide and arsenious oxide may be effected in aqueous caustic soda, the mixture being heated under a reflux condenser. The solution is then acidified and barium hydroxide added to furnish the barium salt of ethylene diarsonic acid, $(CH_2AsO_3Ba)_2$. When an ice-salt bath was substituted in place of heating, acetylene was said to comprise 75 per cent of the yield. In the second procedure, vinyl bromide was stated to be obtained if the arsenious oxide solution was added to the dibromide dropwise rather than by a single operation.

The action of magnesium upon ethylene dibromide was investigated to determine the possibility of forming a Grignard reagent containing two atoms of this metal.[66] The dibromide and the metal were dissolved in dry ether at 5-15°C. It was reported that, under these conditions, the only substances secured were ethylene and magnesium bromide dietherate, with a trace, at most, of a Grignard compound.

It is interesting to note that a mixture of 1 part of methyl bromide, 1 part of ethylene dibromide and 4 parts of liquid carbon dioxide has been suggested as a fire extinguisher.[67]

ETHYLENE DI-IODIDE

Apparently, little information is available upon the formation of ethylene di-iodide from ethylene and iodine. A possible explanation of this phenomenon may be the fact that the di-iodide has not yet been used industrially to as large an extent as have the corresponding dibromide and dichloride.

Among the methods which have been suggested for the production of this iodide are, the introduction of ethylene into a paste composed of iodine and alcohol, and the combination of the olefin and halogen in diffused sunlight in the cold, or in the dark when warmed.[67a]

It has been stated that ethylene di-iodide is formed rapidly when solutions of ethylene and iodine in carbon tetrachloride are exposed to red light.[68] A tungsten lamp having maximum transmission at a wave length of 700 mμ was used to energize the reactants. Solutions containing iodine were thoroughly shaken in a glass apparatus at 25°C. under a constant pressure of ethylene. All air was removed previously from the system by evacuation, and the solution was then frozen with a carbon dioxide-alcohol mixture. The rate of disappearance of iodine was determined by amount of light absorbed. No measurable dark reaction was found to take place over a period of 36 hours. The rate of addition under the influence of light was said to be dependent upon the pressure of the ethylene; further, the rate declined with decreasing concentration of the halogen. It was concluded that since the efficiency of formation of iodine atoms from activated iodine molecules may be small at 700 mμ, the observed photoiodination at this wave length may possibly proceed through the action of excited iodine molecules.

FIG. 133.—Plant for Manufacture of Ethylene Dibromide.

THE DIHALIDES OF PROPENE

Propene Dichloride. Mention has been made, in the section on ethylene dichloride, of the relatively greater velocity of the addition of chlorine to propene than to ethylene. The difference in the reaction rates has been utilized in the fractional chlorination of cracking gas.[69] The process was effected in two stages, the first resulting in the formation of propene dichloride, the second in ethylene dichloride. Two iron towers, packed with turnings of the same metal, were connected through a tube. The mixture of olefin gases was introduced into the first tower which contained chlorine at a temperature of —4°C. In this manner propene dichloride was quickly formed and separated as a liquid while the ethylene was conducted to the second tower where chlorination of this hydrocarbon was effected. The yield of propene derivatives was reported to consist of 85 per cent of propene dichloride and 15 per cent of trichloropropane.

The use of liquid solvents with and without catalysts for the production of propene dichloride has been advocated. In one procedure, propene is reacted with the halogen in the presence of a mixture of tri- and tetrachloropropane.[70] The temperature is maintained at 5°C. and the pressure at 1 atmosphere. The yield of dichloride is stated to be 76 per cent of theoretical. With solvents, such as the ones just mentioned, catalysts consisting of the chlorides of antimony, bismuth, iodine, phosphorus, sulphur, tin or manganese are said to be effective.[71] The chlorine and olefin, at 20°C. and 1 atmosphere pressure, are conducted simultaneously into the liquid containing the catalyst.

The solvent properties of propene dichloride are similar to those of the corresponding ethylene compound. Thus, propene dichloride mixed with *o*-dichlorobenzene[72] or ethylene glycol monoethyl ether[73] is used to effect the separation of wax from lubricating oils. These mixtures are said to have complete solvent action on the oil and practically none on the wax at temperatures ranging from —10 to —22°C. A mixture of 90 per cent of propene dichloride and 10 per cent of methanol is stated to be an effective solvent for cellulose acetopropionate which has been slightly hydrolyzed.[74] Also, the dihalide has been recommended as a selective solvent for removing vinyl resinous materials from cellulose acetate.[75] At a temperature of 20°C. and a contact time of 15 minutes, propene dichloride is reported to dissolve only the vinyl resin, leaving the cellulose acetate unaffected.

Propene dichloride will form azeotropic mixtures with water and may be used for the dehydration of acetic or propionic acid.[76] The dihalide is conducted into a fractionating column near the top while the aqueous acid is introduced at the middle of the same column. The azeotropic mixture distills off, leaving a residue of the anhydrous acid.

Among the uses suggested for propene dichloride is included the preparation of insecticidal compositions. Also, the dihalide has been recommended as a paint remover. In the first case, a 9:1 mixture of propene dichloride and carbon tetrachloride is employed.[77] In the second, *o*-dichlorobenzene and propene dichloride together with small proportions of acetone, benzene and carbon tetrachloride are recommended.[78]

Propene dichloride reacts with sodium cyanide to yield a dinitrile (hydrolyzable to methyl succinic acid) and with aqueous sodium carbonate to give propene glycol.[79] Also, the dihalide may be treated with ammonia to furnish propenediamine. In the latter instance, the olefin dihalide and aqueous ammonia are heated to 120-300°C. The ratio of water to ammonia is suggested as 7:1 by volume.[80]

An attempt has been made to prepare 1,2,3-trichloropropane, $CHCl(CH_2Cl)_2$, by the further chlorination of propene dichloride.[81] Catalysts consisting of calcium and barium chloride, calcium and magnesium oxide, and calcium hydroxide were used in separate experiments. It was found that in the presence or absence of these catalysts, chlorination of propene dichloride leads to the formation of a complex mixture containing mainly 1,1,2-trichloropropane, while 1,2,3-trichloropropane was obtained in a contaminated state and in relatively small quantities. When heated with these catalysts without the addition of chlorine, the dichloride furnishes 1-chloropropene-1 and propadiene ($H_2C{=}C{=}CH_2$) but no allyl chloride from which glycerol might be secured.

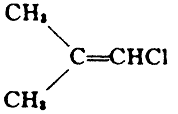
Propene Dibromide. This dibromide may be produced by passing propene into cooled bromine (or bromine water) or by the addition of dilute hydrobromic acid to allyl bromide.[82] On treatment with alcoholic potash, propene dibromide gives rise to a mixture of two isomeric bromopropenes, and on continued treatment a mixture of methylacetylene and propadiene (allene) is obtained.

A comparison of the rates of bromination of propene and ethylene was conducted by Anantakrishnan and Ingold.[83] Experiments were carried out at —78°C. with both reactants in methylene chloride solution and with all light excluded from the reaction zone. Hydrogen bromide was added to mask any autocatalytic effect. In the method a mixture of propene and ethylene was admixed with an amount of bromine insufficient to completely halogenate both compounds. The ratio of the rate constants of the simultaneous reactions was calculated from the composition of the mixture of dibromides formed after complete absorption of all of the bromine. It was reported that the ratios thus obtained are insensitive to the concentrations of the reactants, to the concentration of the hydrogen bromide catalyst, and within considerable limits (from —78 to —35°C.) to a change of temperature. Assuming that the value of the reaction rate for ethylene and bromine is 1, the reaction rate for propene and bromine was stated to be 2, or, the addition of bromine to propene proceeds twice as rapidly as the bromination of ethylene.

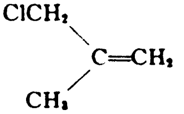
DIHALIDES OF THE BUTENES

Butene Dichloride. The action of chlorine on butene-1 and butene-2 is reported to lead to the production of the dichlorides of these two olefins in the normal way. However, in the case of isobutene, the product is not isobutene dichloride but a mixture of two isomeric chlorobutenes having the configurations:



$(CH_3)_2C{=}CHCl$

and



$(ClCH_2)(CH_3)C{=}CH_2$

Isobutene dichloride, initially formed in this reaction, undergoes immediate decomposition with elimination of hydrogen chloride to yield chlorobutenes. From these data a rather general rule has been drawn, stating that olefins which combine very readily with mineral acids yield monochloroolefins, and those which do not combine readily with mineral acids give rise to the normal addition products on treatment with chlorine.[84]

Butene dichloride has been prepared by the action of chlorine on butene-1 in the cold and in the presence of diffused daylight.[85] Butene-2 may be utilized to furnish a butene dichloride (2,3-dichlorobutane) by combining the former substance with chlorine gas at low temperatures (—10°C.).[86] Under these conditions the yield of butene dichloride is said to be 60 per cent of the theoretical.[87] The dihalide boils in the range 114-120°C. and has d_{20}^{20} 1.116.

Also, it has been reported that butene dichloride is a by-product in the preparation of butene chlorohydrin from butene-2 and chlorourea ($NH_2CONHCl$). Reaction is effected at 15-17°C. in the presence of cupric chloride. The formation of the dichloride is favored by an increase in the acidity of the reaction mixture and ranges between 61 per cent (in 5 per cent hydrochloric acid) to 20 per cent (in 5 per cent acetic acid).[88] As a possible explanation of the observed phenomena it was stated that chlorourea undergoes two simultaneous reactions:

$$NH_2CONHCl + H_2O \longrightarrow HClO + CO(NH)_2$$
$$NH_2CONHCl + HCl \longrightarrow Cl_2 + CO(NH_2)_2$$

Hypochlorous acid combines with butene-2 to furnish butene chlorohydrin, while chlorine adds to the olefin producing butene dichloride:

$$CH_3CH{=}CHCH_3 + HClO \longrightarrow CH_3CHOHCHClCH_3$$
$$CH_3CH{=}CHCH_3 + Cl_2 \longrightarrow CH_3CHClCHClCH_3$$

Also, this olefin dichloride is reported to be secured in 30 per cent yield during the manufacture of the ethyl or methyl ether of butene chlorohydrin. Chlorine gas is conducted into a suspension of powdered sodium hydroxide in ethanol or methanol at a temperature of —5°C. Butene-2 is then added in small quantities to the reaction mixture.[89]

The relatively greater speed of chlorination of a tertiary carbon atom as compared to a secondary or primary carbon atom[90] has been utilized to effect selective chlorination. Thus, a mixture of isobutene (1,1-dimethylethylene) and secondary olefins from cracking gas may be treated with an amount of chlorine insufficient for complete halogenation of all the unsaturated hydrocarbons present. The reaction is carried out at low temperatures (0-60°C.) in the dark and in the absence of moisture. In this manner, 70 per cent of the theoretical amount of 1-chloro-2-methylpropene-2 ($CH_2ClCH_3C{=}CH_2$) and 1-chloro-2-methylpropene-1 ($CH_3CH_3C{=}CHCl$), based on the chlorine input, are said to be obtained.[91] Selective halogenation is also reported to be accomplished by the presence of oxygen in the reaction zone.[92] This substance, it is stated, will inhibit substitution reactions but will not affect addition. For example, a mixture of 56 per cent of butene-2 and 43.4 per cent of normal butane was chlorinated in total darkness. The procedure consisted of placing the hydrocarbons under a reflux condenser and conducting chlorine gas into this reaction zone at the rate of 120 g. per hour for a period of 10 hours. The temperature was maintained between 15° and 20°C., and a small amount of air was recycled in a closed system through the reaction flask. At the end of the reaction period no loss in the volume of air was detected, and the halogenated products were said to consist almost exclusively of butene dichloride. Further, substitution of hydrogen in isobutene by chlorine is said to be favored by atomizing this liquid and mixing it with chlorine gas at low temperatures (0°C.) and in the presence of actinic light. Carbon tetrachloride is incorporated in the reaction zone to carry off the heat furnished by the reaction.[93]

REACTIONS AND USES OF BUTENE DICHLORIDE

The removal of two molecules of hydrogen chloride from butene-2 dichloride (2,3-dichlorobutane) leads to the formation of 1,3-butadiene. In one process, the dihalide was passed through an electric oven at temperatures between 360° and 400°C. Various contact agents were employed, including barium and nickel chloride and aluminum oxide.[94] It was pointed out that barium chloride was the most efficient of the three, a 40 per cent yield of diolefin being obtained. With the others the highest amount of butadiene procured was 15 per cent. Butene dichloride may be further halogenated in the cold in the presence of direct sunlight to furnish hexachlorobutane.[95] If the temperature is raised above 35°C. it is said that two atoms of hydrogen are eliminated from the hexachlorobutane, resulting in hexachlorobutene-2. Alcoholic potassium hydroxide also interacts with the hexachlorobutane, splitting off four molecules of hydrogen chloride to give dichlorodiacetylene, $ClC{\equiv}C{-}C{\equiv}CCl$, an unstable liquid.[96]

One of the uses for which butene-2 dichloride has been recommended is as a solvent, particularly for fats and resins. It may be employed also as a liquid medium in the chlorination of hydrocarbons.[97]

BUTENE DIBROMIDE

The bromination of butene-1 can be accomplished by passage of the olefin into a cooled, aqueous solution of bromine. The product boils at 166.3°C. at 760 mm., melts at —65.4°C. and has d_4^{15} 1.8021.[98] Butene-2 dibromide, existing in several stereoisomeric forms, may be prepared by the same method as butene-1. The ease with which bromine adds to butenes is sometimes utilized in analyzing mixtures of the isomers of this olefin.[99] The mixture is converted to dihalides by treatment with bromine. The resulting substances are then fractionated and their reaction rate with potassium iodide determined.

Young and Winstein[100] distilled a mixture of butene dibromides at 210-230°C. at 760 mm. to determine the extent of isomerization of the dihalides at those temperatures. They reported that the original material had n_D^{25} 1.5118, d_4^{25} 1.7835 and reaction rate constant with potassium iodide, 0.0600. The products obtained from the distillation were said to have n_D^{25} 1.5118, d_4^{25} 1.7828 and reaction rate constant 0.0598. Traces of decomposition due to the loss of hydrogen bromide were ascribed as the cause of the slight change in density, but it was concluded that no appreciable change in properties occurs upon distillation and, therefore, that this analytical method was reliable.

In preparing ethyl propiolic acid, $C_2H_5C{\equiv}CCOOH$, the following method was employed.[101] A mixture of 85 g. of powdered sodium amide and 250 cc. of anhydrous kerosene was incorporated with 94 g. of butene-1 dibromide. The temperature was maintained at 145°C. for a period of 2 hours. At the end of that time 250 cc. of ether were added to the reactants, and a stream of dry carbon dioxide gas bubbled through the solution. Ethyl propiolic acid was precipitated in crystalline form by the latter reagent. The crystals were filtered from the solution, dissolved in water and extracted with ether. A yield of 46 per cent of the theoretical amount of acid is stated to be obtained by this method.

BUTENE DI-IODIDE

Forbes and Nelson[102] point out that iodine will react with butene-1 in dichloromethane or chloroform solution in the presence of actinic light. Solutions containing equimolecular quantities of butene-1 and iodine were placed in the solvents mentioned above and illuminated through 10 cm. of water by incandescent lamps. It was observed that 90 per cent of the iodine disappeared at —60 to —90°C. when dichloromethane was the liquid medium, and that 98 per cent disappeared at —60 to —70°C. if chloroform was the solvent. Further, the halogen was said to be unaffected photochemically by either chlorinated hydrocarbon. Such solutions of photoiodinated butene were illuminated in quartz flasks by a spark passing between tungsten-steel electrodes. In each instance iodine was evolved quantitatively within an hour as determined by titration with sodium thiosulphate at definite time intervals. Another sample of iodinated butene, when kept at 20°C. for a period of four days in the absence of light, had evolved 84 per cent of the iodine which had been chemically combined with butene. The conclusion was drawn that the reaction between the olefin and halogen proceeds to the formation of butene-1 di-iodide in the presence of visible light, and to the decomposition of the dihalide under the influence of ultraviolet light or heat.

DICHLORIDES OF THE AMYLENES

According to Hell and Wilderman[103] interaction of chlorine with amylene-1 is exothermic. They recommend that addition of halogen to this olefin be effected at —17°C. in the presence of actinic light. A mixture of chlorinated derivatives was said to be secured under these conditions. The substances obtained were 31 parts of monochloropentene, 44 parts of amylene-1 dichloride, 10 parts of liquid trichloropentane, and a trace of tetrachloropentane. The first boils at 92-93°C., the second at 130-133°C., and the third at 174-180°C., all under a pressure of 760 mm.

Phosphorus pentachloride was found to interact with amylene-1 to form amylene-1 dichloride, monochloropentene and trichloropentane.[104] It was pointed out that if union of the two reactants was brought about at low temperatures (1 to 5°C.) and the products poured on to ice as soon as the reaction was completed, only pentene-1 dichloride and monochloropentene would be obtained. If, however, the temperature rises above the upper limit mentioned, (above 5°C.) a mixture of the latter substances together with trichloropentane is produced. The latter compound was said to be secured by the displacement of hydrogen in amylene-1 dichloride and by the addition of chlorine to monochloropentene. It was thought that the presence of chloroolefin was due to the heat developed in the reaction, which caused the elimination of a molecule of hydrogen chloride from the amylene-1 dichloride first formed. Further, it was concluded, from the relative proportions of the products, that amylene-1 dichloride loses hydrogen chloride more readily than it takes up another atom of chlorine by substitution, and that chlorine acts more easily on amylene-1 than on monochloropentene.

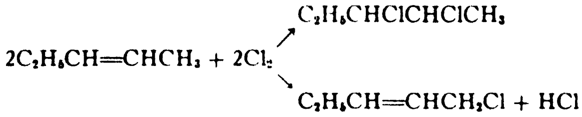
[103] C. Hell and M. Wilderman, *Ber.*, 1891, **24**, 216; *J.C.S.*, 1891, **60**, 533; *Chem. Zentr.*, 1891, 1, 495.

[104] C. Hell and M. Wilderman, *loc. cit.*

The relative proportions of substitution and addition by chlorine interacting with amylene-2 have been investigated.[105] The two reactions, which may be indicated as



$$2C_2H_5CH{=}CHCH_3 + 2Cl_2 \begin{cases} \nearrow C_2H_5CHClCHClCH_3 \\ \searrow C_2H_5CH{=}CHCH_2Cl + HCl \end{cases}$$

were effected by dissolving separately known quantities of the two reagents in carbon tetrachloride and mixing the solutions at temperatures between −10.1° and 25°C. for a period of 15 seconds. Some of the results obtained in this manner are indicated in Table 112. The results are given, not in terms of reaction rates or amounts of the two chlorides, but by induction factors, which represent the ratio of the moles of chlorine producing hydrogen chloride to the moles of chlorine reacting by addition.

TABLE 112.—*The Relative Amounts of Substitution and Addition by Chlorine in Pentene-2.*

Initial Concentrations, Moles Per Liter		Induction Factor
Chlorine	Pentene-2	
0.101	0.097	1.23
0.0464	0.097	1.60-1.64
0.101	0.051	0.57
0.0464	0.051	0.88-0.93
0.00954	0.051	3.04-3.24
0.0464	0.0097	0.72-0.78

It was believed that the above data indicate that substitution was favored by a relative increase in the concentration of the olefin or by a relative decrease in the halogen concentration. The effect of a change of temperature upon the induction factor (within the range investigated) was stated to be very slight. It was also noted that the presence of water, hydrogen chloride or powdered glass produced no change in the rates of addition and substitution.

As a tentative explanation, a chain mechanism based upon competitive reactions for a common intermediate has been suggested. It may be represented as:

$$\begin{aligned} Cl_2 &\longrightarrow 2Cl \text{ (thermally)} \\ C_5H_{10} + Cl &\longrightarrow C_5H_{10}Cl \\ C_5H_{10}Cl + Cl_2 &\longrightarrow C_5H_{10}Cl_3 \\ C_5H_{10}Cl_3 &\longrightarrow C_5H_{10}Cl_2 + Cl \\ C_5H_{10} + C_5H_{10}Cl &\longrightarrow C_5H_9 + C_5H_{10} + HCl \\ C_5H_9 + Cl_2 &\longrightarrow C_5H_9Cl + Cl \end{aligned}$$

---

[105] T. D. Stewart and B. Weidenbaum, *J.A.C.S.*, 1936, **58**, 98; *Brit. Chem. Abs.* **A**, 1936, 310; *Chem. Abs.*, 1936, **30**, 1733.

The action of chlorine upon trimethylethylene has been investigated.[105a] It was stated that when halogenation was effected at −17°C. in the presence or absence of calcium carbonate or sodium bicarbonate, a mixture of chlorine derivatives was obtained. The substances said to be isolated are: 2-chloro-2-ethylpropane; 2-methyl-3-chlorobutene-1; 3-chloropentene-2; 2,3-dichloro-2-methylbutane; 1,3-dichloro-2-methylbutane; 1,2,3-trichloro-2-methylbutane; 1,3-dichloro-2-chloromethylbutane; and 1,2,3-trichloro-2-chloromethylbutane. To explain this phenomenon the explanation was offered that the chlorination of trimethylethylene is accompanied by a number of parallel reactions.

1. Formation of a complex of chlorine and trimethylethylene, of which a portion stabilizes to form 2,3-dichloro-2-methylbutane while another portion splits off hydrogen chloride to furnish 2-methyl-3-chlorobutene-1.
2. Addition of hydrogen chloride both to trimethylethylene, giving 2-chloro-2-ethylpropane, and to 2-methyl-3-chlorobutene-1, yielding 2,3-dichloro-2-methylbutane and 1,3-dichloro-2-methylbutane.
3. Substitution by chlorine in 1,3-dichloro-2-methylbutane, leading to 1,2,3-trichloro-2-methylbutane and 1,3-dichloro-2-chloromethylbutane.
4. Substitution of chlorine in 1,2,3-trichloro-2-methylbutane and 1,3-dichloro-2-chloromethylbutane to furnish 1,2,3-trichloro-2-chloromethylbutane.
5. Isomerization of 2-methyl-3-chlorobutene-1 and 2,3-dichloro-2-methylbutane.

Among the uses for which amylene-1 dichloride has been advocated is the preparation of lubricating oils of low pour point by precipitation of the wax present.[106] When mixed with lubricating oil, the dihalide is reported to give to the oil a high penetrating power.[107] Also, it has been suggested that the dichloride be used to soften road-tar splashes on vehicles.[108] Further, it has been recommended that amylene dichloride be admixed with diamylamine and sodium hydroxide to furnish an insecticidal composition.[109]

AMYLENE DIBROMIDE

Bromine is said to act on amylene at −17°C. to yield amylene dibromide, tribromopentane, tetrabromopentane and isoamyl bromide.[110] The formation of monobromoamylene was believed to be inhibited to a large extent, possibly because the reaction of olefin and bromine is not as exothermic as that with chlorine. Amylene dibromide boils at 175°C. at 760 mm., tribromopentane at 118-119°C. at 12 mm., tetrabromopentane at 148-150°C. at 12 mm., and isoamyl bromide at 254°C. at 760 mm. Amylene dibromide may be further brominated at 100°C. to furnish tri- and tetrabromopentane and higher brominated derivatives. It is interesting to note that the action of bromine upon monobromoamylene in direct sunlight leads to a crystalline tribromopentane which melts at 207°C. Addition of bromine to amylene apparently differs from that of chlorine in that with the former only a trace of monohalogenated olefin is produced and that the higher brominated derivatives are obtained largely from amylene dibromide.

Reactions of Amylene Dibromide. The removal of two molecules of hydrogen bromide from amylene dibromide leads to the production of acetylenes.

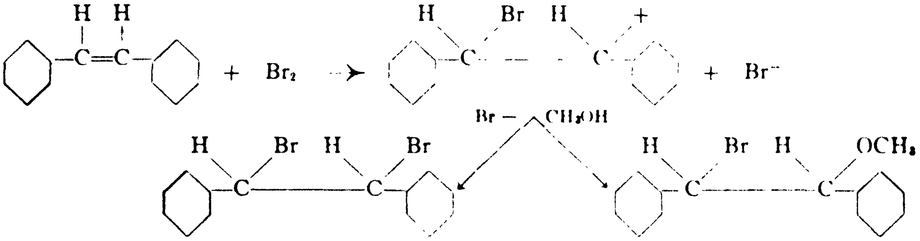
[110] C. Hell and M. Wilderman, *Ber.*, 1891, **24**, 216; *Chem. Zentr.*, 1891, 1, 495; *J.C.S.*, 1891, **60**, 1891.

For example, Hall and Bachman[111] recommend that 1 mole of 1,2-dibromopentane (amylene-1 dibromide) be dehalogenated by use of the requisite amount of potassium hydroxide suspended in a mineral oil. The three substances were heated in a distilling flask connected to a condenser, from which the portion boiling at 39.5-41.0°C. at 747 mm. was retained. This product, pentyne-1, was said to constitute 33 per cent of the theoretical amount. The residue contained monobromoamylene-1 which was converted to the pentyne by heating 1 mole of the latter under a reflux condenser for 5 hours with 3 moles of alcoholic potassium hydroxide.

Bromination of stilbene, $C_6H_5CH{=}CHC_6H_5$, has been reported by Bartlett and Tarbell.[112] Reaction was carried out at 0°C. by dissolving stilbene and bromine separately in methanol and mixing the two solutions. The products of the interaction were stilbene dibromide and stilbene methoxy bromide, so that the mechanism may be expressed as:



The rate of addition was followed by withdrawing samples from the reaction flask, diluting them with 5 times their volume of water containing potassium iodide and titrating the liberated iodine with sodium thiosulphate. The rate of bromination was reported to be diminished by bromine ions but not by hydrogen ions. Therefore, it was concluded that, though stilbene methoxy bromide, C_6H_5CHBr-$CH(OCH)_3C_6H_5$, is the main product, methyl hypobromite is not responsible for its formation. The reason for this statement was said to be the fact that bromine reacts with methanol to form methyl hypobromite, hydrogen ions and bromine ions,

$$Br_2 + CH_3OH \rightleftharpoons CH_3OBr + H^+ + Br$$

and that, if this mechanism was correct, the addition of hydrogen ions should produce the same effect upon the rate of reaction as do bromine ions. This, as was mentioned before, was not observed.

Chapter 21

Production, Properties and Uses of Halohydrins Derived from Simple Olefins

Comparatively little new work is available on the production of halohydrins of the simpler olefins. This is somewhat surprising, in view of the large amount of research which has been directed to the use of this class of compounds, in particular ethylene chlorohydrin, in chemical synthesis. A number of new compounds, however, some of technical importance, have been developed from the alkene chlorohydrins. An example of such is β,β'-dichloroethyl ether, which has found application in the refining of petroleum distillates, particularly lubricating oils.

On the other hand, the preparation of chlorohydrins of the butenes and higher olefinic hydrocarbons has received some attention. Also, several processes dealing with the production of halohydrins of halogenated olefins have also been described.

Ethylene Chlorohydrin

This chlorohydrin, CH_2ClCH_2OH, is made by the well-known reaction between hypochlorous acid and ethylene.[1] One procedure comprises passage of ethylene and chlorine simultaneously into water. In this instance formation of ethylene chlorohydrin can be represented by

$$Cl_2 + H_2O \longrightarrow HOCl + HCl$$
$$C_2H_4 + HOCl \longrightarrow CH_2ClCH_2OH$$

Generally, the concentration of the desired product in the aqueous medium must be kept rather low, say 6 to 8 per cent, otherwise a large proportion of ethylene dichloride may be obtained. Various proposals have been advanced for increasing the yields of chlorohydrin, as, for example, removal of hydrochloric acid (formed as a by-product) by addition of soda ash or incorporation of catalysts, such as cupric chloride or ferric chloride.

Other methods of preparation involve the use of aqueous solutions of hypochlorites, e.g., the sodium or calcium salts. In such cases hypochlorous acid is liberated by the simultaneous introduction of carbon dioxide with gaseous ethylene. The same effect (liberation of hypochlorous acid) may be accomplished also by incorporation of sodium bicarbonate in the reaction mixture. Employment of a solvent which is immiscible with the aqueous medium has been recommended. The presence of this immiscible liquid tends to remove the chlorohydrin from the water layer and thus retard its further interaction with either chlorine or hydrogen chloride.

A procedure developed by Detoeuf,[2] using N-chlorourea as the chlorinating agent, has been described by Likhosherstov and Alekseev.[3] Ethylene is passed through a 5 per cent sulphuric acid solution (at 0°C.) containing N-chlorourea, $NH_2CONHCl$, and cupric chloride. After about five hours a 60 to 70 per cent yield of ethylene chlorohydrin is secured, together with 2 to 2.5 per cent of ethylene dichloride. If additional quantities of N-chlorourea are introduced into the reaction mixture from time to time, concentrations of ethylene chlorohydrin up to 25 to 30 per cent may be produced.

---

[1] For a review of the various methods for carrying out this reaction, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

[2] A. Detoeuf, *Bull. soc. chim.*, 1922, **31**, 102; *Chem. Abs.*, 1922, **16**, 1395; *Brit. Chem. Abs.* **A, 1922**, 196.

Ethylene chlorohydrin is also formed by the interaction of liquid hydrogen chloride and ethylene oxide.[4]

TECHNICAL PROCESSES FOR CHLOROHYDRIN PRODUCTION

The large number of processes which have been developed may be divided into two general types: vapor-phase and liquid-phase operations.[5] The latter are based essentially on the principles mentioned previously, i.e., gaseous ethylene is passed into a liquid medium (water) containing hypochlorous acid. This acid may result from the interaction of chlorine (introduced simultaneously with ethylene) and water, or from dissolved hypochlorites and a weak acid such as carbonic or boric. Generally, the temperature is kept at 30°C. or lower. In vapor-phase methods, the olefin, hydrogen chloride and steam are reacted at temperatures of 100°C. or slightly higher. A large excess of steam is employed to prevent, insofar as possible, the formation of dihalogen derivatives of the hydrocarbon.

Kautter[6] describes an apparatus in which an excess of aliphatic olefin (at atmospheric temperature) is bubbled through an aqueous solution of free hypochlorous acid and hydrochloric acid. Alternatively, the unsaturated hydrocarbon may be passed in a countercurrent manner to a spray of continuously circulated aqueous solution of chlorine and chlorohydrin. Afterwards the chlorohydrin solution is dehydrated by distilling with a paraffin having the same number of carbon atoms as the olefin.

Among the methods used for the interaction of chlorine, water and ethylene may be noted two in which the chlorine gas is added to water in a separate container from the one where the hypochlorous acid solution is treated with olefin. In one case,[7] a mutual exchange of liquids is maintained between the absorbing fluids. In the second procedure[8] interaction takes place by circulating hypochlorous acid solution (maintained at not less than 15 per cent saturation as to chlorine) in countercurrent to the ethylene or propene gas to be absorbed. No neutralizing agent is present in the system.

A method adopted by Dreyfus[9] is to heat a di- or polyhydric alcohol with hydrochloric acid generated *in situ*. For example, monochlorohydrin may be produced by heating in an autoclave at 50° to 60°C. a mixture of glycerol, 90 per cent sulphuric acid and sodium chloride with a small amount of acetic acid as an activator. Addition of more sulphuric acid and continued heating at higher temperatures (200-250°C.) converts the chlorohydrin into the corresponding ether.

[9] H. Dreyfus, British P. 404,938, 1932; *Brit. Chem. Abs.* **B**, 1934, 266; *Chem. Abs.*, 1934, **28**, 4432.

Another procedure[10] involves reacting chlorine and ethylene in an aqueous medium and removing the insoluble chlorinated products from the reaction mixture as they are formed. In an analogous process, addition of ammonia to the reaction mixture is advocated.[11] In this manner the hydrogen halide, formed as a by-product, is converted into ammonium chloride. Or, the hydrochloric acid may be neutralized by conversion into aluminum chloride.[12] In either case the chlorohydrin is recovered by distillation.

Under ordinary conditions of ethylene chlorohydrin production, the reaction mixture is somewhat corrosive. The problems arising from this fact have been met in various ways. A usual method, as will be apparent from the foregoing, comprises incorporation of alkali to neutralize the hydrochloric acid present. Rotshtein[13] suggested that the reaction vessel be made of wood, covered with a phenol-aldehyde resin.

Iskra[14] studied the corrosive properties of a mixture consisting of 7 to 7.5 per cent ethylene chlorohydrin, 5 to 6 per cent ethylene dichloride, 81.5 to 83.5 per cent water, some hydrochloric acid and an excess of chlorine. Lead was quickly attacked at temperatures above 20°C. as were also a large number of alloys and acid-resisting lacquers. Of the former, ferrosilicon, containing 13 to 17 per cent of silicon, gave the most promising results. The most refractory coating was shown to consist of a Haveg type resin,[15] applied as an asbestos-resin plaster on an iron surface. In this instance the resin was only slightly corroded. None of the lacquers tested gave satisfactory results.

A process for preparing alkene chlorohydrins by utilizing the action of sulphur trioxide on the corresponding dichloride is described by Isham and Spring.[16]

An alkene dichloride is treated with sulphur trioxide to obtain a chloroalkylsulphuric chloride which, hydrolyzed with water, forms a chlorohydrin. The latter may then be separated by distillation or by use of a solvent. Application of this method for production of ethylene chlorohydrin from ethylene involves the following reactions:

$$\begin{aligned} C_2H_4 + Cl_2 &\rightarrow C_2H_4Cl_2 \\ C_2H_4Cl_2 + SO_3 &\rightarrow ClC_2H_4SO_3Cl \\ ClC_2H_4SO_3Cl + 2H_2O &\rightarrow CH_2ClCH_2OH + HCl + H_2SO_4 \end{aligned}$$

The quantities of ethylene dichloride and sulphur trioxide used may vary somewhat. However, when employed in molecular proportions (or the dichloride in excess), the best yields of intermediate product with least undesirable by-products and loss of dichloride were secured.

Although the optimum reaction range for the dichloride and sulphur trioxide lies between 35° and 45° C., it was found necessary to maintain a temperature of 5° to 10°C. during the addition of the sulphur trioxide. This was accomplished by precooling the trioxide to just above its solidification point prior to mixing the reactants. In practice, the reaction mass is then removed to a vacuum still where temperature control is possible and separation of unreacted ethylene dichloride and sulphur trioxide is readily effected. After chemical equilibrium is established by holding at about 40°C., removal of a large proportion of the unused dichloride and trioxide serves to concentrate the chloroethylsulphuric chloride. It was noted that the rate of formation of this latter product was considerably increased by the use of reflux reaction between the unreacted ethylene dichloride and sulphur trioxide as these products were driven off.

[15] For the preparation and uses of resins of the Haveg type, see Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, **1935**, 458, et seq.

[16] R. M. Isham and O. Spring, U. S. P. 1,918,967, July 18, 1933, to Doherty Research Co.; *Chem. Abs.*, 1933, **27**, 4815; *Brit. Chem. Abs.* **B**, 1934, 393.

Hydrolysis of the crude chloroethylsulphuric chloride may be carried out in three ways:

1. By mixing with water held near 0°C. and gradually heating to about the boiling point.
2. By adding crude chloride just fast enough to allow heat of hydrolysis to hold the water at its boiling point. (This method requires especial care.)
3. By hydrolysis with cold water which takes longer but normally affords larger yields of ethylene chlorohydrin.

For complete hydrolysis vigorous agitation and the presence of a small amount of sulphuric acid are recommended.

If the hydrolysis is carried out in a distillation unit, the product may be readily recovered by fractional distillation. A constant-boiling mixture of water and ethylene chlorohydrin contains approximately 46 per cent of the latter and boils at 93-94°C. This azeotropic mixture can, in turn, be dehydrated by distillation with ethylene dichloride, which takes out the water in azeotropic mixture at 72°C. Another immiscible solvent available is butyl acetate.

The chlorohydrins of propene, butene and higher olefins may be prepared by the above process. The temperature in these cases must be maintained below 0°C. when reaction with sulphur trioxide is carried out. In addition, cold water is recommended for hydrolysis.

In another procedure,[17] halohydrins are obtained by reaction of the olefin with a tertiary alcohol ester of hypochlorous (or hypobromous) acid in the presence of water. Ethylene, for example, gives ethylene chlorohydrin and tertiary butyl alcohol when passed into a mixture of *ter*-butyl hypochlorite and water at 18 to 22°C. This method is reported equally applicable to the preparation of the chlorohydrins and bromohydrins of propene, isobutene, isoprene and cyclohexene. The tertiary alcohol esters of the hypohalous acids are prepared by passing chlorine or bromine into the aqueous alcohol containing sodium hydroxide.

An alcohol that is easily dehydrated, e.g., *ter*-butyl alcohol, can be used to prepare an alkene chlorohydrin[18] if treated in the presence of water with a hypohalogenous acid. Instead of the acid a hypohalite ester, such as butyl hypochlorite, may be used if it has an alkyl group next to the hypohalogenous acid radical.

Alkene chlorohydrins are formed along with aliphatic esters when olefin diesters of saturated aliphatic monocarboxylic acids are treated with hydrochloric acid and an alcohol.[19] For example, ethylene glycol diacetate treated with hydrochloric acid and ethyl alcohol gives ethylene chlorohydrin and ethyl acetate.

PROPERTIES AND USES OF ETHYLENE CHLOROHYDRIN

A physico-chemical study of ethylene chlorohydrin has been made by Radulescu and Muresanu.[20] Hydrolysis of this compound was found to be unimolecular, and the reaction constants at different temperatures were determined as follows:

	Reaction Constant
At 56°C.	0.0000036
At 65°C.	0.0000080
At 79°C.	0.0000408
At 99°C.	0.00029

These values were not affected by the presence of calcium chloride, sodium chloride or hydrogen chloride. Equivalent quantities of ethylene glycol and hydrogen chloride, in solutions varying in concentration from 0.2 to 2N, reacted very slowly at 99°C. to give the chlorohydrin.

Indices of refraction of ethylene chlorohydrin were found to be

At 10°C.	1.44551
At 15°C.	1.44382
At 20°C.	1.44212
At 25°C.	1.44123

Density determinations gave the following values:

At 15°C.	1.2014
At 20°C.	1.1981
At 25°C.	1.1954

Ethylene chlorohydrin has been found to possess a high degree of toxicity as an insecticide.[21] Ginsburg[22] reports, after testing the effect of a number of fumigants on codling-moth larvae, that this halohydrin was second only to liquid hydrocyanic acid in order of potency. It was observed, however, that the percentage kill was considerably reduced as the temperature was lowered. It has likewise been noted[23] that the rate of hydrolysis of starch by the enzyme, amylase, is increased by ethylene chlorohydrin; but, according to Denny,[24] the accelerating effect of this latter compound on the growth of dormant buds is not directly due to its stimulating influence on the activity of the enzyme.[25] Ethylene chlorohydrin has been suggested as a refining agent for rosin[26] to be used in the manufacture of glaze for paper. Further, it has been recommended that the chlorohydrin be employed to remove naphthenic compounds from crude petroleum.[26a]

Butene Chlorohydrins

Batalin and Ugriumov[27] have described the preparation of butene-2 chlorohydrin by two different methods. In the first, after the manner adopted by Gomberg,[28] a yield of 50 to 60 per cent in 7 to 8 per cent concentration was obtained. A modification of McElroy's[29] process proved more convenient and gave 60 to 65 per cent of the chlorohydrin and 10 to 30 per cent of the dichloride. In each case the utilization of butene-2 was 85 per cent. The product was separated from the reaction mixture by distillation with steam under reduced pressure.[30]

The ethers of butene-2 chlorohydrin are formed when chlorine is passed into an alcoholic solution of sodium hydroxide at —5°C. while butene-2 is being gradually added.[31] Excess of chlorine (25 per cent) and of alkali (30 per cent) are necessary. The alkali chloride and unchanged alcohol may be removed from the reaction mixture by repeated washings with water and the product then dried with calcium chloride and distilled. By this procedure 60 to 70 per cent yields of the ethers can be obtained, with 25 to 35 per cent of dichlorides as by-products. The properties of the methyl, ethyl and isobutyl ethers of butene-2 chlorohydrin are given in Table 113.

TABLE 113.—*Monoalkyl Ethers of Butene-2 Chlorohydrin.*

The preparation of isobutene chlorohydrin from *ter*-butyl hypochlorite and *ter*-butyl alcohol has been briefly discussed earlier in this chapter.[32]

CHLOROHYDRINS OF SEVERAL HIGHER OLEFINS

The formation and properties of some of the higher homologues of ethylene chlorohydrin have been described by Nilsson and Smith.[33] These workers prepared the α-dimethyl-, trimethyl-, tetramethyl- and α-diethyl-ethylene chlorohydrins and determined their rates of hydrolysis in neutral and alkaline solutions at 18°C. For a homologous series the rate in neutral solution appeared to be unaffected by the substitution of a methyl group for a hydrogen atom. However, in alkaline media, a considerable increase was observed when the same change in composition was made. These results are in accordance with Michael's[34] rule.

Godchot, Mousseron and Granger[35] synthesized a number of cyclic chlorohydrins by the action of hypochlorous acid on the corresponding cyclic olefin.

2-Chlorocyclopentanol. A mixture of the *cis* and *trans* isomers of this compound is formed when hypochlorous acid is allowed to react with cyclopentene. Some separation can be effected by careful fractionation of the product, although the *cis*-2-chlorocyclopentanol obtained (b.p. 44°C. at 15 mm.) probably contains a small proportion of 1,2-dichlorocyclopentane as an impurity. *trans*-2-Chlorocyclopentanol boils at 84°C. at 15 mm. and has d_{16} 1.174 and n_D^{16} 1.4832. When heated with 25 per cent aqueous alcohol, it is rapidly and quantitatively converted into *trans*-cyclopentane-1,2-diol. Similar treatment leaves the *cis*-compound unchanged.

2-Chlorocyclohexanol. As with cyclopentene, a mixture of two stereoisomeric chlorohydrins is produced by the action of hypochlorous acid on cyclohexene. *cis*-2-Chlorocyclohexanol is a liquid with b.p. 76°C. (15 mm.)[36] and n_D^{16} 1.4860. Boiling aqueous alcohol has little effect on it. *trans*-2-Chlorocyclohexanol, on the other hand, is a solid melting at 29°C. It boils at 87°C. at 15 mm. and is slowly changed by aqueous alcohol at 90°C. into *trans*-cyclohexane-1,2-diol and cyclopentylformaldehyde. The latter furnishes a semicarbazone melting at 123 to 124°C.

---

1-Methyl-4-chlorocyclohexan-3-ol. Two stereoisomers of this composition may be isolated from the mixture of four chlorohydrins resulting from the reaction between hypochlorous acid and 1-methyl-Δ^3-cyclohexene. One of these (b.p. 79°C. at 16 mm.) is unchanged on boiling with water at 90°C. Another (b.p. 101 to 102°C. at 16 mm.) is partially converted under these conditions into *trans*-1-methylcyclohexane-3-4-diol (m.p. 63°C.) and 1-methyl-3-cyclopentylformaldehyde. The semicarbazone of this aldehyde melts at 133°C.

2-Chlorocycloheptanol. The action of hypochlorous acid on cycloheptene appears to give only one chlorohydrin. This compound, b.p. 98°C. (16 mm.), d_{19} 1.1351 and n_D 1.4948,[37] is completely transformed by boiling with aqueous alcohol into cyclohexylformaldehyde. The semicarbazone of this aldehyde melted at 167° to 168°C.

2-Chlorocyclooctanol. This substance boils at 128° to 130°C. at 20 mm. pressure. Prolonged heating with aqueous alcohol at 90°C. produces cyclooctadiene without the formation of a glycol or of the aldehyde of cycloheptane.

Bartlett and his co-workers prepared the chlorohydrins of methylcyclopentene and methylcyclohexene by two procedures. In the first, with Grignard's reagent, the *cis* isomer was formed, while the *trans* compound resulted from the action of hypochlorous acid on the cyclic monolefin.

2-Chloro-1-methylcyclopentanol.[38] The *cis* compound is obtained when 2-chlorocyclopentanone reacts with methyl magnesium bromide. It boils at 61 to 64°C. at 7 mm. and has d_{24} 1.131 and n_D^{24} 1.477. The corresponding characteristics for the *trans* isomer (from the olefin and hypochlorous acid) are b.p. 50° to 57°C. (8 mm.), d_{24} 1.059 and n_D^{24} 1.4709.

2-Chloro-1-methylcyclohexanol.[39] By the interaction of 2-chlorocyclohexanone with methyl magnesium bromide a 55 to 82 per cent yield of *cis*-2-chloro-1-methylcyclohexanol may be secured. This chlorohydrin boils at 73° to 75°C. at 15 mm. and has d_{25} 1.0995 and n_D^{25} 1.4775. It remains unchanged on distillation with quinoline, but after refluxing for one hour methylcyclohexadiene is produced. The action of 33 per cent sodium hydroxide solution (or heating with water at 200°C.), gives methylcyclopentyl ketone. *trans*-2-Chloro-1-methylcyclohexanol, from hypochlorous acid and methylcyclohexene, is a liquid of b.p. 90 to 95°C. at 28 mm., d_{26} 1.006 and n_D^{25} 1.4850. Shaking with 20 per cent cold sodium hydroxide solution gives 1-methyl-1,2-epoxycylohexane. Refluxing with 14 per cent sodium hydroxide for three hours produces *trans*-1-methylcyclohexane-1,2-diol.

When dimethylpentenol[40] is treated with hypochlorous acid, the product obtained is not the expected chlorohydrin of tetramethylglycerol, viz:

---

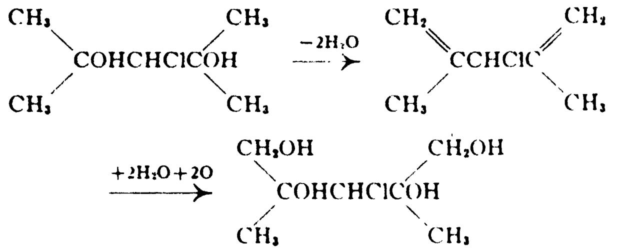
The latter compound may be formed as an intermediate, but apparently loses water and becomes oxidized at the points of unsaturation, thus:

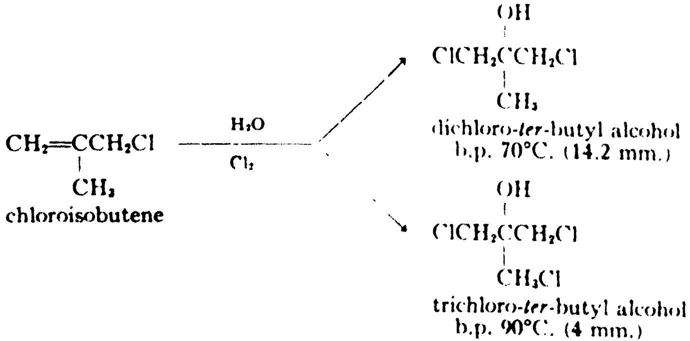


The product finally obtained, a tetrahydric alcohol, melts at 132°C.

In a process described by Cook[41] for the preparation of higher chlorohydrins which are insoluble in water, the liquid olefin, e.g., octene, is treated with an aqueous solution of hypochlorous acid, prepared from sodium bicarbonate and chlorine. The weak hypochlorous acid solution employed, containing not less than 0.75 per cent of HOCl, is intermittently regenerated while out of contact with the olefins and chlorohydrin in order to prevent the formation of dichloride.

CHLOROHYDRINS OF HALOGENATED OLEFINS

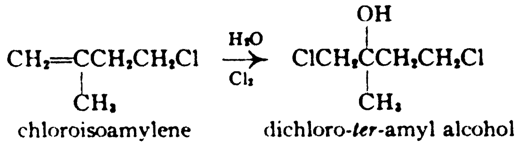
Some higher chlorohydrins of monohalogeno-alkenes have been prepared by Groll and Hearne.[42] The unsaturated monohalide, containing not less than four carbon atoms and having the halogen atom attached to saturated carbon, is treated with hypochlorous acid. An addition takes place in the usual way at the double linking, unless the latter is attached to tertiary carbon, when chlorination alone takes place. In some cases both hypochlorous acid and chlorine are added on. The reaction takes place in a similar manner when chlorine water or alkyl or aralkyl hypochlorites and water are used instead of hypochlorous acid. Some examples given by Groll and Hearne are presented below. For instance, chloroisobutene furnishes both dichloro- and trichloro-*ter*-butyl alcohol.



[41] L. W. Cook, U. S. P. 1,904,677, April 18, 1933, to Texas Co.; *Brit. Chem. Abs.* B, 1933, 998; *Chem. Abs.*, 1934, **28**, 3482.

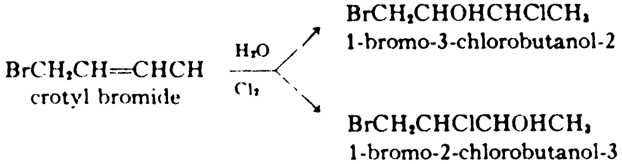
[42] H. P. A. Groll and G. Hearne, British P. 435,096, 1935, to Bataafsche Petroleum Maatschappij; *Brit. Chem. Abs.* B, 1935, 1129; *Chem. Abs.*, 1936, **30**, 1067. French P. 789,289, 1935; *Chem. Abs.*, 1936, **30**, 1812. U. S. P. 2,062,002, Nov. 24, 1936, to Shell Development Co.; *Chem. Abs.*, 1937, **31**, 708.

Chloroisoamylene, on the other hand, yields only one product.



$$\underset{\text{chloroisoamylene}}{\underset{\displaystyle CH_3}{CH_2{=}\overset{}{C}CH_2CH_2Cl}} \xrightarrow[Cl_2]{H_2O} \underset{\text{dichloro-}\textit{ter}\text{-amyl alcohol}}{ClCH_2\overset{\displaystyle OH}{\underset{\displaystyle CH_3}{C}}CH_2CH_2Cl}$$

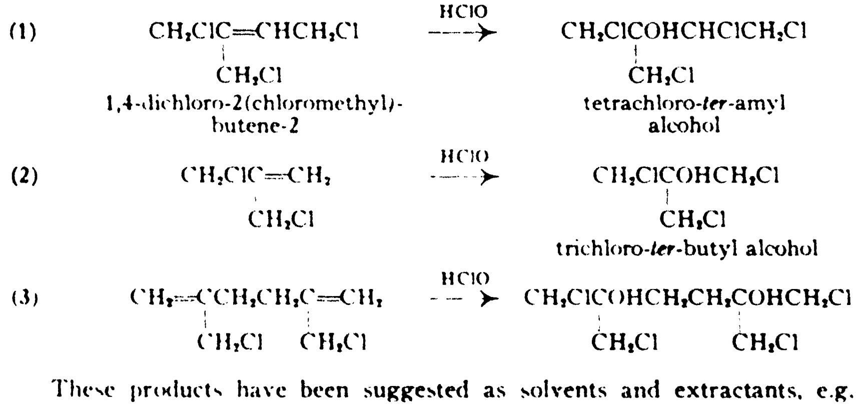
Crotyl bromide, a halogenated straight-chain olefin (as contrasted with branched-chain olefins), gives two halogenated alcohols.



$$\underset{\text{crotyl bromide}}{BrCH_2CH{=}CHCH} \xrightarrow[Cl_2]{H_2O} \begin{cases} BrCH_2CHOHCHClCH_3 & \text{1-bromo-3-chlorobutanol-2} \\ BrCH_2CHClCHOHCH_3 & \text{1-bromo-2-chlorobutanol-3} \end{cases}$$

These above-mentioned reactions take place at room temperature. The resulting polyhalogenated tertiary alcohols are intermediates for the preparation of unsaturated aldehydes and ketones, polyhydric alcohols and other derivatives which may be used for making resins or perfumes.

Polyhalogenated olefins may be substituted for the monohalogenated analogues, in which case alcohols containing three or more halogen atoms per molecule are obtained.[43] Combinations of this type can be represented in the following manner:



$$(1)\quad \underset{\text{1,4-dichloro-2(chloromethyl)-butene-2}}{CH_2Cl\underset{\displaystyle CH_2Cl}{C}{=}CHCH_2Cl} \xrightarrow{HClO} \underset{\text{tetrachloro-}\textit{ter}\text{-amyl alcohol}}{CH_2Cl\underset{\displaystyle CH_2Cl}{C}OHCHClCH_2Cl}$$

$$(2)\quad CH_2Cl\underset{\displaystyle CH_2Cl}{C}{=}CH_2 \xrightarrow{HClO} \underset{\text{trichloro-}\textit{ter}\text{-butyl alcohol}}{CH_2Cl\underset{\displaystyle CH_2Cl}{C}OHCH_2Cl}$$

$$(3)\quad CH_2{=}\underset{\displaystyle CH_2Cl}{C}CH_2CH_2\underset{\displaystyle CH_2Cl}{C}{=}CH_2 \xrightarrow{HClO} CH_2Cl\underset{\displaystyle CH_2Cl}{C}OHCH_2CH_2\underset{\displaystyle CH_2Cl}{C}OHCH_2Cl$$

These products have been suggested as solvents and extractants, e.g., in the refining of mineral oils and purification of refinery and manufactured gases. The polyhalogenated alcohols may also be hydrolyzed to polyhydric alcohols.

Groll and Hearne[44] have converted polyhydric alcohols containing a greater number of halogen atoms than hydroxyl groups into oxy-compounds having fewer chlorine atoms. The reaction may be accomplished by contact with a non-oxidizing basic metallic oxide or hydroxide or by means of basic organic compounds such as amines. For example, dichlorotertiary butyl alcohol treated with a slurry of lime produced an 80 per cent yield of methyl epichlorohydrin (1) and a lesser amount of β-methyl glycerol (2). These changes may be indicated as follows:

---

(1)

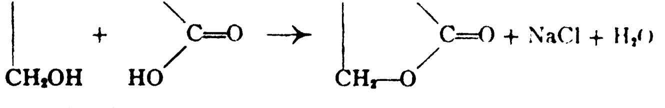
(2)

The epichlorohydrin boiled at 122°C. under atmospheric pressure. It represents a class of compounds useful as solvents for cellulose esters, as extractant agents in the separation and refining of mineral and vegetable oils, and as chemical intermediates for the production of a variety of other organic substances.

Chlorohydrins in Chemical Snytheses

Due to the presence of a reactive halogen (chlorine) atom in the molecule, 1,2-halohydrins are important intermediates in many chemical syntheses. For example, distillation of these compounds, particularly in the presence of solid alkalies, furnishes olefin oxides, and hydrolysis gives the corresponding glycols.[45] By interaction with ammonia (or amines) or with sodium alcoholates are obtained substituted amines or ethers, respectively. Possessing a hydroxyl group, chlorohydrins exhibit many of the characteristic properties of alcohols, e.g., esterification with organic acids to chlorinated esters.

Steimmig and Wittwer[46] report that carbonic acid esters are obtained in higher yields by the action of sodium bicarbonate on chlorohydrins than from glycols and phosgene or chlorocarbonic esters. They recommend that operations be carried out at atmospheric or slightly superatmospheric pressure. Thus, ethylene glycol carbonate is obtained in 80 per cent yield by heating equimolecular proportions of ethylene chlorohydrin and sodium bicarbonate for several hours. When no more sodium bicarbonate remains, the unchanged ethylene chlorohydrin and the water formed during the reaction are removed by distillation. The hot residue is then filtered from the sodium chloride, and, on cooling, a mass of crystals of ethylene glycol carbonate separates.



1,2-Propene glycol carbonate, a viscous liquid having specific gravity of about 1.21, dissolves with difficulty in water. It boils at 110°C. (at 12 mm. pressure) with partial decomposition. To prepare this compound two moles of 1,2-propene chlorohydrin are heated to boiling under reflux with one mole of sodium bicarbonate, together with a quantity of ethylene chloride or benzene. These last-named solvents form binary mixtures of low boiling point with water, which is thus continuously removed as it is formed during the reaction. Operations are stopped when all the alkali has disappeared. The chlorohydrin is distilled off and the hot residue filtered. From the resulting mixture of 1,2-propene glycol and

---

[45] For a review of the reactions of chlorohydrins, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934. See also Chapters 22 and 23.

[46] G. Steimmig and M. Wittwer, U. S. P. 1,907,891, May 9, 1933, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1933, 27, 3721.

1,2-propene glycol carbonate, the latter (about 30 per cent of the mixture) is obtained in a pure state by fractional distillation followed by freezing of the distillate.

When an aqueous solution of ethylene chlorohydrin is treated with an alkali metal resorcinolate at 50-55°C. for 24 hours under a reflux, resorcinol β-hydroxyethyl ether is obtained.[47] This material is a solid, melting at 83.1-83.4°C., boiling at 214°C. (20 mm.), and soluble in water, ether and benzene. Motwani and Wheeler[48] point out that either the mono- or di-β-hydroxyethyl ether may be obtained by regulating the proportions of reactants. These ethers furnish the corresponding mono- or di-β-chloro derivatives, respectively, on treatment with phosphorus pentachloride.

On heating the halohydrin with thionyl chloride, β-chloroethyl sulphite is formed.[49] Komissarov[50] studied this reaction and found that on using a slight

$$2ClCH_2CH_2OH + SOCl_2 \longrightarrow (ClCH_2CH_2O)_2SO + 2HCl$$

excess (5 per cent) of thionyl chloride in the cold, β-chloroethyl chlorosulphinate is first produced.

$$ClCH_2CH_2OH + SOCl_2 \longrightarrow ClCH_2CH_2OSOCl + HCl$$

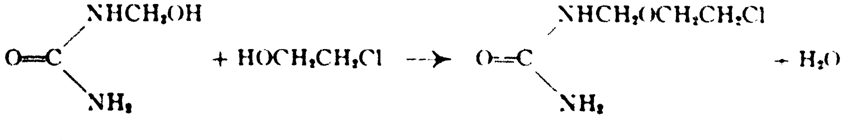
If more of the halohydrin is then added and the mixture heated for 3 hours at 50° to 60°C., β-chloroethyl sulphite is obtained.

$$ClCH_2CH_2OSOCl + ClCH_2CH_2OH \longrightarrow HCl + (ClCH_2CH_2O)_2SO$$

The latter may be reconverted into the chlorosulphinate (at room temperature) by the action of thionyl chloride.

β-Chloroethyl sulphite boils at 147-150°C. at 10 mm., and at 117.5-118°C. at 4 mm. It has d_4^{20} 1.4255, d_0^0 1.444, and n_D^0 1.481. β-Chloroethyl chlorosulphinate boils at 93° to 95°C. at 40 mm. and at 84 to 85°C. at 20 mm. and has d_4^{20} 1.5010.

Condensations with Ureas. Synthetic resins and condensation products resembling linoxyn and waxes, which can be employed in the manufacture of lacquers and plastics, are made by condensing urea or methylol urea with ethylene chlorohydrin.[51] Reaction with monomethylol urea is carried out at 90°C. in the presence of a small proportion of urea nitrate. It proceeds according to the equation:



$$O{=}C\begin{matrix}\diagup NHCH_2OH\\ \diagdown NH_2\end{matrix} + HOCH_2CH_2Cl \longrightarrow O{=}C\begin{matrix}\diagup NHCH_2OCH_2CH_2Cl\\ \diagdown NH_2\end{matrix} + H_2O$$

The product may then be combined (a) with sodium acetate to form an ester; (b) with sodium methoxide to give an ether; or (c) with the sodium salt of the acid methyl ester of oxalic acid to give a di-ester.

Reaction of the monomethylol urea-ethylene chlorohydrin condensation product with sodium linoleate at 120°C. for 12 hours gave a yellow-brown resin resembling linoxyn and suggested as a binding agent in laminated and molded articles.

Reactions with Mercaptans. Ethylene chlorohydrin may also be employed in the preparation of certain aliphatic sulphides of high molecular weight, as, for example, the product from α-dodecylthiol and the halohydrin. These have a soapy character and may be used in the production of detergents, emulsifying agents and various textile assistants, as well as in the rubber and pharmaceutical industries.[52]

Windus and Shildneck[53] report that methyl mercaptan (dissolved in alkaline medium) combines with ethylene chlorohydrin to furnish β-hydroxyethyl methyl sulphide. In this instance, the mercaptan was made by decomposition of dimethyl isothiourea sulphate[54] with aqueous sodium hydroxide.

$$HN{=}C(SCH_3)NH_2]_2 \cdot H_2SO_4 + 2NaOH \longrightarrow HN{=}CNH_2 \cdot NHCN + 2CH_3SH + Na_2SO_4 + 2H_2O$$

The hydroxy thioether may be converted into the corresponding β-chloroethyl methyl sulphide by the action of thionyl chloride.[55]

$$CH_3SCH_2CH_2OH + SOCl_2 \longrightarrow CH_3SCH_2CH_2Cl + SO_2 + 2HCl$$

Sulphur-containing compounds are said to be obtained by the interaction of acetals of ethylene chlorohydrin and ammonium, alkali or alkaline-earth sulphides or polysulphides.[56] Combination of the reactants may proceed in the presence of water.

Arsenic Derivatives. Soare[57] has described the preparation of β-haloethylarsines from ethylene chlorohydrin. He gives the following details for making β-bromoethyl arsenic dibromide: 100 g. of ethylene chlorohydrin were added with constant stirring to a solution of sodium arsenite obtained by adding 100 g. of arsenious oxide to 120 g. of sodium hydroxide in 300 cc. of water. The temperature of the mixture was maintained at 5 to 10°C. and the progress of the reaction followed by taking a test portion from time to time, acidifying with hydrochloric acid, neutralizing with sodium bicarbonate and titrating the arsenious oxide with 0.1*N* iodine. After 3 to 4 hours it was found that 80 to 85 per cent of the arsenic had combined. Stirring was then stopped and the sodium chloride formed removed by filtration. The filtrate was neutralized (using Congo red as an indicator), concentrated in vacuo at a low temperature, filtered, and extracted with absolute alcohol. The residue, consisting of impure β-hydroxyethanearsonic acid, $HOC_2H_4AsO(OH)_2$, was next converted into β-hydroxyethylarsenous oxide, HOC_2H_4AsO, by heating an aqueous solution on the water bath at 60°C. for 2 hours in an atmosphere of sulphur dioxide. Treatment in the cold with potassium bromide and sulphuric acid produced a brown liquid which was extracted with chloroform. From the residue, β-bromoethylarsenic dibromide was finally obtained by distillation under reduced pressure. This dibromide is a colorless crystalline solid (m.p. 36°C., b.p. 110°C. at 25 mm.) which slowly decomposes unless kept perfectly dry. On treatment with warm aqueous sodium hydroxide, it yielded ethylene quantitatively.[58]

Reaction with Amines. β-Diethylaminoethyl alcohol is prepared by heating diethylamine and ethylene chlorohydrin[59] in the presence of sodium hydroxide in an autoclave for 3 hours at 160°C.:

$$(C_2H_5)_2NH + ClCH_2CH_2OH + NaOH \longrightarrow (C_2H_5)_2NCH_2CH_2OH + NaCl + H_2O$$

Hartman[60] reports a yield of 68 to 70 per cent of the theoretical amount by this method. According to Headlee, Collett and Lazzel,[61] this amino-alcohol is a liquid with the following physical properties: b.p. 160°C. (741 mm.), 100°C. (80 mm.), 96°C. (73 mm.) and 55°C. (10 mm.); n_D^{25} 1.4389, d_{abs}^{25} 0.0405, and surface tension of 27.50 dynes per cm. at 26.5°C.

In a process developed by Lehmann[62] equimolecular proportions of the amine and halohydrin are allowed to react in a liquid medium (e.g., methyl alcohol) containing an alkali. Mono-N-alkanol derivatives of the aromatic diamines or polyamines are formed. These are described as being basic in character, readily soluble in water or alcohol, difficultly so in ether, and insoluble in aliphatic hydrocarbons. They furnish salts which may be dissolved in water. The alkanol amines are suggested as intermediates in the preparation of dyes.

Another field for the use of ethylene chlorohydrin is in the preparation of compositions for waterproofing fabrics. One component of such mixtures may be nonwetting protective colloids[63] resulting from the condensation of ethylene chlorohydrin (or ethylene oxide) with various insoluble organic compounds containing a hydroxyl or amino group and at least six carbon atoms. Acrylic acid esters, their homologues and polymers may be employed in the production of resins for use in the manufacture of laminated safety glass, lacquers, varnishes and electrical insulating media.[64] A synthesis of these esters, developed by Bauer,[65] is based on the use of ethylene chlorohydrin as a starting material. This is reacted with sodium cyanide to furnish the nitrile. The latter, in turn, is converted into an ester of acrylic acid by treatment with an alcohol in the presence of an acid. The reaction involved may be summarized in the two equations:

$$CH_2OHCH_2Cl + NaCN \longrightarrow CH_2OHCH_2CN + NaCl$$
$$CH_2OHCH_2CN + ROH + H_2SO_4 \longrightarrow CH_2{=}CHCOOR + NH_4HSO_4$$

β,β'-DICHLORODIETHYL ETHER

This compound, $ClCH_2CH_2OCH_2CH_2Cl$, is formed when ethylene chlorohydrin is treated simultaneously with chlorine and an excess of ethylene at 80°C.[66] At the end of the reaction, water is added and the mixture distilled. An 85 per cent yield of the ether is reported, ethylene dichloride being formed as a by-product. The ether is a liquid of boiling point 178°C., freezing point $-$ 51.7°C., and $d\,^{20}_{20}$ 1.222. Its toxicity has been investigated by Schrenk, Patty and Yant,[67] who concluded that the odor and the irritant properties of this substance give ample warning of its presence in concentrations likely to prove dangerous.

In various ways this chloro-ether has assumed commercial importance. It reacts with metallic polysulphides (e.g., Na_2S_4) to give products resembling rubber.[68] Condensed with substituted phenols or naphthols in the presence of sodium hydroxide it furnishes plasticizers which may be incorporated in cellulose ester lacquers and analogous compositions.[69] Other industrial applications are as a liquid medium for the hydrolysis of cellulose acetate,[70] as an ingredient in cellulose acetate dopes and lacquers,[71] and in the preparation of morpholine derivatives.[72] N-substituted morpholines are prepared by the action of β,β'-dichlorodiethyl ether on a primary amine, such as aniline, in the presence of an inorganic base. These are suggested as dye intermediates, rubber antioxidants, acid and corrosion inhibitors.

By the action of fused potassium hydroxide on β,β'-dichlorodiethyl ether in an atmosphere of ammonia, Major and Ruigh[73] produce practically pure divinyl ether, $CH_2{=}CHOCH{=}CH_2$. Lott[74] accomplishes the same conversion by adding the dichloroether under pressure to a solution of potassium hydroxide in diethylene glycol at 210-240°C. Divinyl ether is a liquid boiling[74a] at 28.3°C. at 760 mm. Much interest has been shown in the use of this ether in anesthesia.[74b] The compound is said to be more toxic than diethyl ether but less so than chloroform.[74c] Since with divinyl ether, anesthesia is rapidly induced, easily maintained and subsequent recovery is rapid, the substance is considered widely useful in operative procedures of short duration.[75] The ether containing a small percentage of a non-volatile stabilizer (about 0.01 per cent) and about 3.5 per cent ethanol as an anti-freeze is known as vinethene.[75a] Suggested stabilizers include polyphenols, e.g., hydroquinone, and aromatic amines, e.g., N.N′-diphenyl phenylene diamine and phenyl-α-naphthylamine.[75b]

β-Chloroethyl-β′-chloroisopropyl ether, $ClCH_2CH_2OCH(CH_3)CH_2Cl$, a liquid boiling at 65°C. (8 mm.), is prepared from ethylene chlorohydrin, chlorine and propene.[75c] Other bis-β-dichlorodialkyl ethers[76] may be synthesized by employing the appropriate olefin and alkene chlorohydrin. According to Cox,[77] the reaction, in the presence of water, between ethylene chlorohydrin, chlorine and ethylene, at temperatures between 20°C. and 100°C., leads to the formation of β-chloroethyl-β-chloroethoxyethyl ether, $ClCH_2CH_2OCH_2CH_2OCH_2CH_2Cl$. This water-insoluble liquid, suggested for high-pressure lubrication, boils at 230°C. at 760 mm., and at 118°C. at 10 mm.

Interaction of β,β′-dichlorodiethyl ether with a Grignard reagent,[78] such as magnesium-phenylbromide, in xylene, at 140°C., results in the formation of di-β-phenylethyl ether, b.p. 162-165°C. (7 mm.). By analogous reactions such compounds as the following may be prepared: γ,γ′-diphenyldipropyl ether, b.p. 200-210°C. (5 mm.) and β-chloro-β′-phenyldiethyl ether, b.p. 100-110°C. (2 mm.). Subsequent treatment of the diethyl ethers yields substituted alcohols or alcoholic derivatives.

THE CHLOREX PROCESS

The use of β,β′-dichlorodiethyl ether in the refining of lubricating oils has been referred to previously. The value of this solvent is enhanced by its physical properties, the high specific gravity making for rapid separation of the two phases formed with oils, and its relatively low boiling point rendering recovery a comparatively simple matter. Furthermore, extraction temperatures are not high (10° to 52°C.), so that plant costs and evaporation losses are both low. The main effect of Chlorex treatment is to improve the viscosity index[79] of the lubricant, which may be increased even when the original figure is high as in the case of Pennsylvania residua. Also, some treated distillates are reported to exhibit a high resistance to sludging and oxidation.[80]

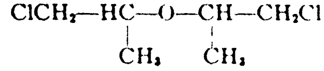
Bennett[81] separates the naphthenes from the paraffins of a lubricating oil by a single extraction with, for example, 6 parts of β,β'-dichlorodiethyl ether. Page[82] recommends diluting the oil with a light hydrocarbon such as propane, butane or propene before extraction. Other diluents which may be employed are benzene or trichloroethylene.[83] In some instances, the distillate may be subjected successively to different extracting agents, e.g., liquid sulphur dioxide followed by Chlorex.[84] Another modification comprises distilling the treated oil between each extracting operation. Liberthson[85] points out that agitating the halogenated ether with oils containing dispersed "green" acids and dissolved "mahogany" acids[86] (resulting from fuming sulphuric acid refining under sulphonating conditions) effects coagulation and precipitation of the former. Mahogany acids remain in solution in the ether layer which forms when the oil-ether mixture is allowed to settle. In this way separation of the two types of sulphonated materials may be accomplished. Page[87] suggests dichloroethyl ether as a liquid medium for the removal of oil from paraffin wax. The same chloro-ether is incorporated by Tijmstra and McKittrick[88] in a composite selective solvent for dewaxing petroleum oils.

Other chlorinated ethers, such as β,β'-dichlorodipropyl ether and β-β'-dichlorodiisopropyl ether, either alone or in admixture with propane, butane, propene or acetone, are also efficacious in the removal by selective extraction of naphthenic and other undesirable constituents of mineral or lubricating oils.[89]

Bis(β-chloroisopropyl) Ether

The preparation and properties of this compound have been described by Wickert.[90] Propene chlorohydrin (500 g.) is treated with concentrated sulphuric acid (100 g. of d 1.84) in a 5-liter flask under reflux regulated to allow removal of the water formed in the reaction. After heating to boiling for 3 hours, an equal volume of water is added to the contents of the flask. Distillation without rectification is then carried on until the distillate is free from oily particles. The ether settles as an oily layer; after separation it is dried over potassium carbonate and distilled under reduced pressure. The final product, β,β'-dichlorodiisopropyl ether, may be indicated by formula in the following manner:



$$\mathrm{ClCH_2{-}\underset{\displaystyle CH_3}{\underset{|}{HC}}{-}O{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH_2Cl}$$

It is a water white liquid, boiling at 187.1°C. Its density, d_{20}, is 1.1127.

BROMOHYDRINS DERIVED FROM OLEFINS

A few bromohydrins have been described, notably those obtained from cyclohexene and its derivatives. A general method for the synthesis of bromohydrins by the use of esters of hypobromous acid has been referred to previously.[91]

2-Bromocyclohexanol. Preparation of this compound was carried out by Hunter and Marriott[92] in the following manner. A solution of hypobromous acid was first made by gradually mixing equimolecular quantities of mercuric oxide and bromine in ice-cold water. This solution, after being rapidly filtered, was added (in slight excess) to cyclohexene. With constant agitation and cooling, the product was distilled with steam, dried and then fractionated in vacuo. 2-Bromocyclohexanol was obtained as a heavy, colorless liquid of boiling point 103° to 104°C. at 18 mm.[93] It is said to turn black very rapidly, even in the dark. A certain proportion of this compound is also formed in the preparation of *1-methyl-2-bromocyclohexan-1-ol.*[94]

Cyclohexene may be treated with the mixture of hypobromous acid and methyl hypobromite. The latter is obtained by shaking a 5 per cent methyl alcohol solution of bromine with a solution of silver nitrate in ethyl alcohol. A 50 to 60 per cent yield of 1-methyl-2-bromocyclohexan-1-ol, b.p. 76° to 77°C. (10 mm.), n_D^{20} 1.4884, d_4^{20} 1.3314, is secured. At the same time some 2-bromocyclohexan-1-ol is formed.[95] The product is obtained purer, but in smaller yield, if a methyl hypobromite reagent is used. This material is prepared by shaking a 5 per cent solution of bromine in methyl alcohol with an excess of finely divided solid silver nitrate. The nitric acid set free should be almost neutralized with calcium carbonate and the excess silver nitrate nullified by the addition of potassium acetate. It was not possible to replace the silver nitrate by sodium, barium or calcium carbonate, nor by oxide of mercury.

Methyl hypobromite alone was used in the preparation of all the following compounds:

(β-Methoxy-γ-bromopropyl) benzene (from allyl benzene and methyl hypobromite) which is a liquid of d_4^{20} 1.3191, n_D^{20} 1.5365.

(α-Metoxy-β-bromopropyl) benzene, b.p. 87° to 88°C. (0.4 mm.), n_4^{20} 1.3090, n_D^{20} 1.5338, is formed in 50 per cent yield from propenylbenzene.

α-Methoxy-β-bromodihydroanethole, obtained from anethole in 70 per cent yield, has b.p. 115° to 116°C. (0.15 mm.), d_4^{20} 1.3181 and n_D^{20} 1.5391.

Bromomethoxycyclohexene as made from cyclohexa-1,3-diene was an impure material boiling at 66° to 72°C. under 0.2 mm. pressure. A similar yield (45 to 50 per cent) of the same oily product was obtained with bromoacetamide as reagent instead of methyl hypobromite.

Chapter 22

Production, Properties and Uses of Simple Glycols

The glycols, or dihydric alcohols, may be of two kinds, (a) those derived by the hydroxylation of olefins and which are designated α- or 1,2-glycols because the hydroxyl groups are attached to adjacent carbon atoms, and (b) those in which the hydroxyl groups are mutually more remote, as in trimethylene glycol. The large supplies of ethylene in gases from cracking operations have been found to be a raw material for the synthesis of ethylene glycol, and have thereby caused great interest in this compound.[1] Methods for the formation of glycols, of which 1,2-dihydroxyethane or ethylene glycol is the most common, depend either upon mild oxidation of the unsaturated hydrocarbon at its double bond, or hydrolysis of derivatives of alcohol.

Direct hydroxylation of an alkene may be accomplished by the use of such agents as potassium permanganate, Caro's acid (H_2SO_5) and persulphuric acid or by employment of osmium tetroxide to catalyze a mild oxidation by potassium chlorate. However, hydrolysis of derivatives of the glycols is more frequently employed.

PRODUCTION OF ETHYLENE GLYCOL

Among the substances from which glycols may be prepared are the dihaloethanes, ethylene halohydrins and glycol esters. Heating a dihaloethane and aqueous sodium carbonate in an autoclave at pressures up to 100 atmospheres is one mode of procedure. Thus, Klebanskii and Dolgopol'skii[2] found that an 82 per cent yield of glycol may be obtained by saponifying 200 g. of ethylene dichloride with 220 g. sodium carbonate for 4 hours at 150°C. and 52 atmospheres pressure. By using sodium acid carbonate ($NaHCO_3$) and heating for 36 hours at 150°C. under 58 atmospheres pressure a 92.5 per cent conversion was secured. No improvement was observed when emulsifiers such as petroleum sulphonic acids, sodium oleate or sodium stearate were added to the reaction mixture. Under semi-commercial conditions, yields of 85 to 90 per cent were procured by employing temperatures of 175° and 195°C. and 100 atmospheres pressure. Some vinyl chloride, which was separated by absorption in xylene, was also found. Weihe[3] has suggested effecting reaction between ethylene chloro- or bromo-hydrin or ethylene di-bromide or -chloride by treating with sodium hydroxide and simultaneously adding carbon dioxide.

Aqueous potassium carbonate has been used for hydrolysis of ethylene dibromide.[4] In this instance a mixture of glycol (in largest proportion) and vinyl bromide is formed, the latter by elimination of hydrogen bromide from the dibromo hydrocarbon. In the presence of a solution of potassium carbonate in equal parts of ethanol and water, the vinyl halide was the major product. On the other hand a solution of sodium hydroxide in absolute alcohol gave vinyl bromide as the only product. The latter reaction is said to be purely bimolecular, and proceeds according to the equation.

$$BrCH_2—CH_2Br + NaOH \longrightarrow CH_2{=}CHBr + H_2O + NaBr.$$

The reaction velocity, however, was considerably reduced by the addition of water. It also varied with temperature in accordance with the expression:

$$k_{t_1} = k_{t_0}e^{r(t_1-t_0)}$$

where k_{t_1} and k_{t_0} are the reaction constants at the new temperature, t_1, and the original temperature, t_0 respectively, r is a constant and e is 2.71828 (the base of the natural logarithms). The value of k_{t_1} was not affected by the presence or absence of water.

Other methods have been proposed for hydrolysis of ethylene dichloride. Askenasy and Heller,[5] for example, used barium carbonate, water and the dihalogen derivative. The mixture was heated between 160°C. and 180°C. for less than an hour (0.5 to 0.75 hour) to give 75 per cent yields of glycol together with 12 per cent of acetaldehyde. The latter was recovered from the vapors which were removed from the autoclave during the reaction. Any higher boiling substances removed in this manner, such as the glycol or dihalide, are returned to the reaction. Another procedure is to mix ethylene dichloride with water to form a constant boiling mixture and conduct the latter over a bed of a water-insoluble carbonate, such as calcium carbonate.[6] The temperature of the reaction chamber (Fig. 134) is maintained at 160-170°C. by superheated steam. The vapor products of the hydrolysis are led to a separator where unreacted ethylene dichloride is removed from glycol. The former may be recycled.

In contrast to the results obtained by other workers, Wada and Sato[7] obtained only 43 per cent glycol by saponifying ethylene dichloride. By hydrolysis of ethylene chlorohydrin at 150°C. and 17 atmospheres pressure, however, they secured 71 per cent yields of glycol. These results confirmed the conclusion of Takahashi and Makishima[8] that hydrolysis of the dihalide gave poorer yields than did that of the chlorohydrin. The procedure of the latter investigators was to treat ethylene dichloride or halohydrin for 10 hours with aqueous sodium carbonate at normal pressures and at temperautres between 60° and 80°C.

Dunstan and Birch[9] have suggested that glycol may be prepared from chlorohydrin in a continuous manner. The chloroethanol in aqueous solution is heated between 105° and 150°C. under pressure with a non-caustic alkali such as sodium carbonate. Ethylene oxide may form to a limited extent only. Lewis[10] recommends that the hydrolysis be carried out in steps as shown in the diagram (Fig.

135) but at normal pressure. For example, the chlorohydrin and alkali are united in the mixing kettle (1). The temperature is so low (room temperature) that no reaction takes place, but the mixture passes by gravity feed through each of the kettles 2, 3, 4, and 5. These kettles are heated to progressively higher temperatures and agitated so that the saponification proceeds more readily in the latter than the first kettles. The temperatures in kettles 2, 3 and 4 may, for example, be maintained at 140 to 160°F., 170 to 180°F. and 200-210°F. respectively, and in kettle 5 the mixture is at its boiling point. The vapors from all the kettles are scrubbed to recover organic substances such as olefin oxides or chlorohydrins. The washings are returned to the mixing kettle (1).

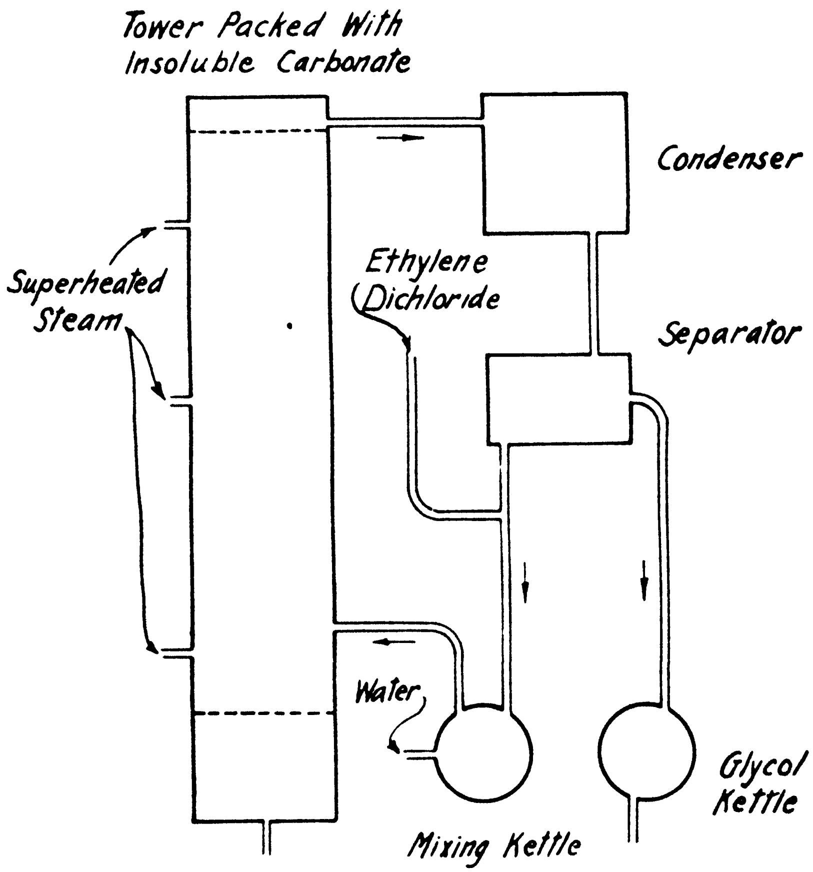

FIG. 134.—Sketch of Equipment for Hydrolysis of Ethylene Dichloride to Ethylene Glycol. (R. de M. Taveau)

In addition to the methods for the hydroxylation of olefins which were mentioned earlier,[11] Skärblom[12] has proposed the interaction of ethylene, water and oxygen carried out in the presence of iodine or its compounds at about 100°C. and under superatmospheric pressures.

PROPERTIES OF ETHYLENE GLYCOL

Ethylene glycol is a colorless, viscous[13] liquid with a sweet taste. It is completely miscible with water and, in fact, strongly hygroscopic. At 760 mm. pressure it boils at 197.2°C.[14] The density (at 20°C. referred to water at 4°C.) is 1.1140.

FIG. 135.—Flow Diagram for Stepwise Hydrolysis of Ethylene Chlorohydrin. (H. A. Lewis)

The refractive index for the yellow sodium (D) lines is 1.43192 at 20°C. and 1.43172 at 25°C. The vapor pressure, p, is given by the equation

$$\log_{10} p = \frac{A}{T} + B$$

where T is the temperature in degrees absolute and A and B are constants whose values depend somewhat upon the temperature. Between 90° and 130°C. the values are 3193.6 and 9.7423, respectively, whereas between 130° and 197.2°C. they are 2994.2 and 9.2477, respectively.

Romstatt[15] has investigated the densities and refractive indices at different temperatures as well as initial boiling points of aqueous mixtures of glycol. The heat of dilution at 15°C. and the contraction of volume[16] were also measured. Some of Romstatt's results are given in Table 114.

The vapor pressures of ethylene glycol and water mixtures have been ascertained by Trimble and Potts,[17] and also the composition of liquid and vapor phases.

---

A modified Othmer still (Fig. 136) was employed for obtaining the vapor phase, the analysis being made refractometrically. The vapor pressure was expressed by the equation

$$\log_{10}p = A + \frac{B}{T},$$

where T is absolute temperature and p the vapor pressure. A and B are constants whose values depend upon the composition of the liquid.[18] The ratio of glycol in vapor and liquid varies only slightly with pressure, although it changes markedly with change in composition of the liquid. Some of the results, together with the values computed for A and B in the above equation, are given in Table 115.

Chemically, ethylene glycol behaves as an alcohol. It may be oxidized, for example, electrochemically at a smooth platinum anode,[19] to give an hydroxyaldehyde. Its homolog, propene glycol, as well as phenylethylene glycol, under similar conditions give the corresponding hydroxy ketones. Another reaction of electrochemical oxidation is splitting a primary or secondary glycol such as ethylene or 2,3-butene glycol into two aldehyde molecules. A ditertiary glycol, such as pinacol, will be oxidized to two ketone molecules by this reaction. These latter reactions are more pronounced at higher potentials.

Concentrated hydrochloric acid (hydrous medium) converts ethylene glycol into the chlorohydrin or dichloride, whereas hydrogen chloride (anhydrous medium) appears to form first the epoxide (ethylene oxide) and subsequently the chloro compounds.[20]

According to Kedrinskii and Skornyakova[21] solutions containing ethylene and propene glycol should be analyzed by oxidation with dichromate as well as by density and water determinations. If salt is also present it may be estimated by the Vollrath method (see Chapter 50).

TOXICITY OF ETHYLENE GLYCOL

There is considerable difference of opinion as to the possibility of the exhibition of poisonous properties by glycol.[22] The evidence appears to be that its toxicity depends very largely upon the conditions under which it is tested. Mancini,[23] for example, has observed that the minimum lethal dose is from 3 to 9 cc. per kilogram of body weight depending upon the experimental animal used. He stated that it could be administered in reasonable doses without fear of toxic action. Injections intramuscularly are said to cause neither persistent pain, irritation or abscess. Applications to the mucosa cause a slight disturbance, whereas there is no effect when applied to the skin. The possible objectionable results are hemolysis (cf. Chapter 53), oxaluria[24] and decrease in blood pressure. Wiley, Hueper and van Oettingen[25] have pointed out that concentrations of glycol as high as 300 mg. per 1000 liters of air have no toxic effects on rats or mice, and probably would have none on man. A concentration of 0.5 mg. per 1. is saturated. Brown[26] has also directed attention to the toxicity of both glycol and dioxane.[27]

APPLICATIONS OF ETHYLENE GLYCOL

Ethylene glycol has found use in many fields.[28] It has been employed as an antifreeze in automobile cooling systems and also as a preservative. It is a solvent for many organic substances in which respect it resembles ethanol. Thus Rae[29] has obtained a strongly tinctorial extract from cudbear (a lichen), and from other natural sources such as saffron, red rose petals, Brazil wood, carmine, buttercups and *Centaurea montana* (a blue-flowered plant native to the Pyrenees). In most cases the presence of water was harmful, but deeper tints were obtained from madder and henna in the presence of water than without it. Glycol could not be used for preparing extracts of litmus, alkanet root or gamboge. The glycol has been proposed as a solvent for insecticidal compositions containing pyrethrins.[29a] Ethylene glycol (5 per cent by volume) has been suggested as a selective solvent for the more readily oxidizable constituents of gasoline (cf. Chapter 40), thus reducing the gum- and color-forming tendency of the fuel.[30] Dehydration of diethyl ether may be effected by mixing the latter with 20 to 50 volume per cent of glycol and distilling. The ether is said to contain less than 0.6 per cent water after this treatment. Other substances which are hygroscopic and do not form azeotropic mixtures with ether may also be used, such as propene glycol, diethylene glycol, glycerol, and triethanolamine.[31]

Lockspeiser[32] has suggested that glycol be used either alone, or with 10 per cent ethanol to prevent the formation of ice on airplane propellers during flight. In experimental tests on a Hart and a Gordon airplane, 1.5 and 1.7 pints of liquid were used per hour, respectively. Milliken[33] reported, as a further application of glycol, that it is possible to reduce the viscosity of nitrocellulose by digestion with glycol or glycerol (of 95% or more concentration) at 160°C. and atmospheric pressure. According to Blount and Boardman,[33a] a soluble oil may be prepared by mixing 14 parts sodium soaps (e.g. those from corn-oil acids), 6 parts water, 64 parts mineral oil, 10 parts water-white rosin, 4 parts of a polyhydric alcohol (such as glycol or diethylene glycol) and 2 parts of a monoalkylated dihydric alcohol such as ethylene glycol monoethylether.

Tatter[34] has suggested that a mixture containing 50 volume per cent glycol together with water (37 to 45 per cent) and a sulphonated oil (13 to 5 per cent) be used as the hydraulic fluid in brakes. Other compositions intended for this same purpose comprise the dihydric alcohol mixed with the sodium salt of the sulphuric ester of castor oil,[34a] with furfurol or other furan derivatives,[34b] or with lard oil (containing 10 to 15 per cent free fatty acids) and a large proportion of ethanolamines (40 to 100 per cent of the weight of the lard oil).[34c] Cox[35] proposed a mixture of ethylene and propene glycols, or other polyhydric alcohols, as a heat or pressure transfer medium. Furthermore, according to Cox and Clapsadle[36] a mixture of 60 to 30 per cent ethylene and 40 to 70 per cent diethylene glycols may be used as a heat transfer medium in cooling systems and as a pressure transfer medium in hydraulic brakes.

Glycol (95 per cent) has been recommended as an antifreeze in conjunction with 5 per cent or less of a mixture containing ethanolamine salts of fatty acids.[37] It has also been suggested as an absorptive liquid for ammonia,[38] as a solvent for extracting colored substances from rosin,[39] together with an oil as a vehicle for an abrasive containing bentonite,[40] and for addition to solid carbon dioxide to decrease the size of crystals and thereby improve its mechanical properties.[41] An interesting application of ethylene glycol is as the electrolyte for a battery.[42] The cell contains two electrodes, one of aluminum, magnesium, beryllium, cadmium, zinc or an alloy or amalgam of these or of chromium, silver or silver plated metals, and the other of cuprous, ferric, vanadic, plumbic or cadmic oxide, sulphide or selenide, or carbides of iron or nickel. The electrolyte consists of ethylene glycol, glycerol or a derivative of one of these to which has been added a small proportion of a weak organic acid such as lactic, malic or tartaric. A battery of this type is said to be particularly applicable for maintaining a grid-bias on a vacuum tube (a so-called "c-battery").

Esters of Ethylene Glycol

The esters of glycol have been the subject of many investigations.[43] The dinitrate is used extensively in admixture with nitroglycerine to form explosives which have lower freezing points and less susceptibility to shock than glycerol trinitrate itself. Nitration is carried out in much the same manner as in the preparation of nitroglycerine. A modification proposed by Brown[44] comprises the control of the reaction temperature by addition of a hydrocarbon which is unaffected by the nitrating mixture, and which is volatilized by the heat of reaction. Isopentane was suggested as fulfilling the requirements.

There are three general methods which have been employed for the preparation of the glycol mono- and di-esters of aliphatic acids. These are:

a. Reaction of salts of acids with ethylene dihalides.
b. Esterification of glycol with acids or their anhydrides.
c. Condensation of epoxides with acids or anhydrides.

For example, glycol diacetate may be prepared by any of these three methods. Thus, it has been synthesized in 20 per cent yield by passing vapors of glycol and acetic acid in a stream of nitrogen over active carbon containing small amounts of phosphoric acid.[45] Although better yields were secured at 130° to 150°C., it was found necessary to work with temperatures of 160° to 170°C. to obtain a satisfactory reaction velocity. The only product from this procedure was the diacetate whether one or two moles of acetic acid were used per mole of glycol. The monoacetate, which may be employed as a component of a fluid for hydraulic brakes,[46] may be prepared by the esterification of either the glycol or ethylene oxide (epoxide).

The aliphatic esters have found employment in various ways, particularly as solvents. Dreyfus[47] proposed that a diester of glycol be decomposed by heating between 450° and 600°C. with the formation of an acid anhydride. In this manner ethylene glycol diacetate is reported to be converted into acetic anhydride. Isobutyrates of glycol or diethylene glycol are reported to be plasticizers for cellulose acetate.[48] The glycol derivatives of saturated or unsaturated fatty acids such as glycol stearate have been suggested as ingredients for soap-free shaving preparations.[49] On the other hand, Lomakin and Smirnov[50] have proposed as a lubricant the products resulting from esterification of bone grease with ethylene glycol at temperatures below 130°C. Adams[51] recommended the ethylene and propene glycol esters of branched-chain aliphatic acids of 12 to 20 carbon atoms as bactericides and bacteriostatic agents.

The work of Meerwein and Sönke[52] on the trichloroacetates is of interest. These investigators prepared trichloroacetyl glycol from ethylene oxide and trichloroacetic acid. Because of its strongly acid nature and vigorous reaction with diazomethane, they believed that the compound was an ortho-ester:

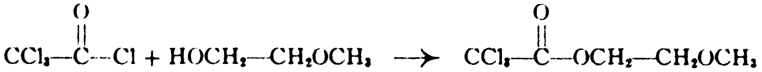
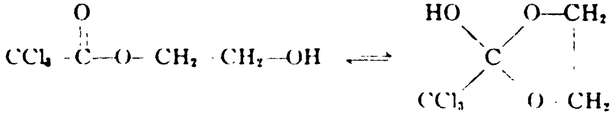
Abs.* **A**, 1933, 1273; *Chem. Abs.*, 1933, **27**, 4215. See also H. Meerwein and G. Hinz, *Ann.*, 1930, **484**, 1; *Brit. Chem. Abs.* **A**, 1931, **206**; *Chem. Abs.*, 1931, **25**, 1484.

As a confirmation of this structure, the straight-chain trichloroacetyl glycol methyl ether was made from trichloroacetyl chloride and 2-methoxyethanol.



$$CCl_3{-}\overset{O}{\overset{\|}{C}}{-}Cl + HOCH_2{-}CH_2OCH_3 \longrightarrow CCl_3{-}\overset{O}{\overset{\|}{C}}{-}OCH_2{-}CH_2OCH_3$$

The product was very different in chemical properties from the supposed ortho-ester. For example, alcoholysis (by heating with alcohol) of the ortho-ester resulted in replacement of the methyl group by another alkyl residue, whereas the straight-chain compound should give 2-methoxyethanol and an alkyl trichloroacetate. Further experiments on the reactions of ethyleneglycol-monotrichloroacetate (such as with ammonia, acetyl or thionyl chloride) showed that it was a tautomeric mixture (in uncertain proportions) of the two possible compounds having the structures:



2-hydroxyethyl trichloroacetate — *2-hydroxy-2-trichloromethyl 1,3-dioxolane.*

In this connection, Hibbert and Greig[53] investigated the nature of the product obtained in endeavoring to prepare glycol trichloroacetates. They also reported a compound with a dioxolane structure, which was said to decompose on heating at 100° to 110°C. to give ethylene carbonate and chloroform. This result, however, was not confirmed by Meerwein and Sönke. The physical properties of some of the 2-alkoxy-2-trichloromethyl-1,3-dioxolanes prepared by these latter workers are given in Table 116.

TABLE 116.—*Properties of 2-Alkoxy-2-trichloromethyl-1,3-dioxolanes.*

Alkyl Group	Boiling Point Pressure	Boiling Point Temperature	Density at 20° 4°	Index of Refraction n_D^{20}
Methyl (m. p., 78-8.5°)	10 mm.	112-3°C.	1.486	1.45652 (n_D^{100})
Ethyl (m. p., 26.4°)	10 mm.	119-20°C.	1.429	1.47846
Propyl	2.1 mm.	99°C.	1.370	1.47635
Butyl	5.85 mm.	125.5°C.	1.321	1.47439

GLYCOL ESTERS OF POLYCARBOXYLIC ACIDS

The esters of polyhydric alcohols and polybasic acids are well known to exhibit a resinous character because of the tendency to form very large molecules.[54] On the other hand many of the simpler esters of glycol are said to be plasticizers. For example, Gabriel and Swallen[55] obtained a neutral product by the interaction of phthalic anhydride and ethylene glycol, using sulphuric acid as a catalyst. The product may be used as a plasticizer with nitrocellulose. Nonresinous esters of dibasic acids and polyhydroxy compounds may be synthesized from the alcohol and acid anhydride by reacting them in the presence of a tertiary organic base. By employing one mole equivalent of base for the corresponding amount of acid anhydride, it is possible to obtain acid esters of polyhydric alcohols,[56] which may be reacted further with monohydric alcohols or partially esterified cellulose. Dreyfus[57] has suggested that hydroxyalkyl alkoxyalkyl esters of polycarboxylic acids such as:

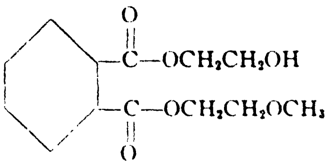
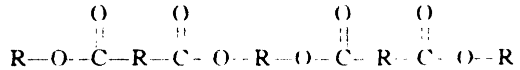
[56] French P. 761,591, 1934, to Kodak-Pathé; *Chem. Abs.*, 1934, 28, 4432.

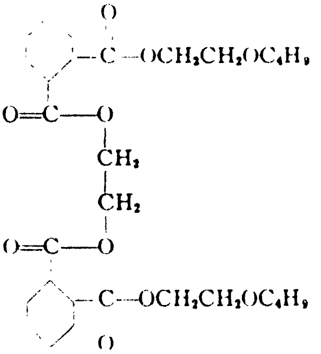


be used as plasticizers. Frazier[58] suggested the preparation of esters of the type



$$R{-}O{-}\overset{\overset{O}{\|}}{C}{-}R{-}\overset{\overset{O}{\|}}{C}{-}O{-}R{-}O{-}\overset{\overset{O}{\|}}{C}{-}R{-}\overset{\overset{O}{\|}}{C}{-}O{-}R$$

by heating 2 moles of a polycarboxylic acid such as phthalic ($HO{-}CO{-}R^1{-}CO{-}OH$) with 1 mol of a glycol ($HO{-}R''{-}OH$) such as an alkene or polyalkene glycol and subsequently esterifying with a monohydric alcohol ($R{-}OH$). An example of a product of the kind is di-β-butoxyethyl ethyleneglycol diphthalate,



Ethers of Ethylene Glycol

Of about equal importance with the esters of glycol are the ethers and their derivatives which have been employed in numerous instances as solvents and diluents. For example, glycol monoethyl ether has been used in duplicator fluid together with water and ethanol for wetting the wax impressions prior to printing.[59] Mixtures of this ether with castor oil and alkyl derivatives of toluene sulphonamide[59a] are suggested as fluids for hydraulic brakes. North[60] has employed the oleates of glycol methyl- and butylethers as plasticizers. On the other hand, Seymour[61] employed the formals of ethylene, propene or diethylene glycol or glycerol monochlorohydrin as solvents for cellulose derivatives and in binding layers of cellulosic materials. The products were formed by heating the glycol with formaldehyde (or its polymers) in the presence of an acid condensing agent such as hydrogen chloride, sulphuric or phosphoric acid or ferric chloride.

A small proportion (1 part) of monoethyl ether of ethylene glycol has been used together with beeswax (70 parts), stearic acid (20 parts) and paraffin (10 parts) in making wax for molded candles.[62] It has also been employed admixed with *o*-dichlorobenzene and an ether of diethylene glycol, as a solvent for oils during dewaxing by chilling to —23°C.[63] Furthermore, its acetate has been utilized in conjunction with an immiscible liquid (e.g., water) in refrigerating apparatus, the acetate furnishing a liquid medium interspersed between any crystals formed.[64]

The toxicity of the monoethyl ether of ethylene glycol has been investigated.[64a] It was reported that the ether has a relative toxicity of approximately the same order as carbon tetrachloride and benzene, when considering acute poisoning. Further, it was stated that air, saturated at 20°C. with the vapor of the ether, possesses a disagreeable odor and also produces moderate eye irritation. If these properties are heeded as warning of the occurrence of a potentially dangerous atmosphere and exposure is avoided, it is believed that acute poisoning will not occur.

The monoethers, including the butyl ether of glycol, have been suggested for addition (0.1 to 5.0 per cent) to a mineral oil in conjunction with 1.0 to 5.0 per cent of an aluminum soap of stearic, palmitic or behenic acid.[65] Boyle[66] and Neilson[67] have recommended the monobutyl ether of ethylene glycol in compositions intended to clean metals prior to painting. Boyle employs phosphoric acid, the ether (as an oil solvent) and a wetting agent, whereas Neilson used phosphoric acid and saponin (a glucoside) together with an optional amount of the ether. Glycol monoethers have also been advocated as emulsifying assistants for mixtures of soap and benzene, or its homologs, and other hydrocarbon materials[68] and as a solvent in preparing a coating composition from chlorinated rubber and an organic abietate.[69]

The naphthyl ethers of glycol have been synthesized by heating glycols with sodium naphthoxide or with naphthol and sulphuric acid at about 120°C.[70] On the other hand, the benzyl ethers of glycol (and glycerol) may be obtained by heating the polyhydric alcohol with benzyl chloride and powdered sodium hydroxide.[71] In an analogous manner ethers may be made from dodecyl, myristyl, cetyl or oleyl halides, or those of alcohols obtained by reduction of resins, or resinic or naphthenic acids.[72] The ethers of aliphatic polyhydric alcohols may be esterified with aliphatic acids containing more than 7 carbon atoms to give plasticizers, such as 2-ethoxyethyl caprylate.[73] Cyclic acetals may be prepared on condensation of an aldehyde and a polyhydric alcohol by heating with benzene so that water is removed as it forms.[74] Internal ethers of glycol such as dioxane and its isomers are considered more fully in Chapter 23. Glycol dialkyl ethers are said to result on heating a monoalkyl ether either by itself or with a monohydric alcohol in the presence of sulphuric acid.[75]

The tertiary ethers of glycol have been prepared by condensation of a tertiary olefin, such as *2*-methyl-butene-*2* or isobutene, with glycol in the presence of sulphuric acid.[76] In this way the mono-*ter*-amyl ether (b.p. 50°-55°C. at 3 mm.) and the various *ter*-butyl ethers listed in Table 117 may be synthesized.

TABLE 117.—*Tertiary Butyl Ethers of Glycol and its Monoalkylethers.*

Alcohol	Boiling Point of the *ter*-Butyl Ether
Ethylene Glycol	152.5°
Glycol methyl ether	131-2°
Glycol ethyl ether	147.5°
Glycol *n*-butyl ether	83.4° (20 mm.)
Glycol *ter*-butyl ether	171°
Propene glycol	151-3°

These ethers and diethers are said to be useful in dyeing, explosives, as lubricants, cooling liquids for internal combustion engines, and as solvents and plasticizers. The esters of glycol ethers and hydroxy acids may be further esterified by acids to give substances which are said to be plasticizers.[77] Alkoxyalkyl esters of polybasic acids such as adipic, sebacic[78] or benzoylbenzoic[79] have been proposed.

POLYETHYLENE GLYCOLS

The formation of an ether by elimination of water (one molecule) from two molecules of glycol leads to the production of diethylene glycol or *2,2'*-dihydroxydiethyl ether. This reaction is assisted by various catalysts, as for example, heating glycol to 190°C. with 0.3 per cent by weight of iodine.[80] Compounds of as high molecular weight as decaethylene glycol (mol. wt. about 458) may be obtained Another procedure involves the interaction of ethylene oxide and glycol. It has been suggested that the dichloride of a polyethylene glycol be condensed with the monosodium salt of a polyethylene glycol. For example, 171 g. diethylene glycol and 100 cc. of ether were treated with 3.5 g. sodium metal until the latter had dissolved. To this solution was then added 24.8 g. of hexaethylene glycol dichloride prepared from 33.0 g. hexaethyleneglycol, 18.5 g. pyridine and 27.8 g. thionyl chloride. The solution of sodium salt and glycol chloride was heated at 70°C. for 5 hours, at 100°C. for 4 hours and finally at 160°C. for 40 hours. A yield of 68.5 per cent was obtained.

decaethylene glycol (b.p., 220-223°C. at 0.010 mm.)

The polyethylene glycols are solvents with low volatility and are miscible with water. They may be incorporated in a fatty acid soap for use with chloroform or carbon tetrachloride in dry-cleaning.[81] By heating diethylene glycol monoethyl ether to above 250°F. with boric acid and a base (such as ammonium, sodium or potassium hydroxide or an ethanolamine) a liquid is obtained which may be used as the electrolyte in an electrolytic condenser.[82] The polyglycerols (higher than 3 molecules) incorporated with 10 to 30 per cent water and a small proportion of a hygroscopic substance (other than the polyglycerols) are suggested as lubricants for valves and stopcocks.[83]

The derivatives of polyethylene glycol have been used in many ways. A large number of mixed esters and ethers including alkoxyacetates and alkyl and tetrahydrofurfuryl ethers have been advocated as solvents for refrigerants such as monofluorodichloromethane or methyl chloride.[84] Merrill[85] prepared the arsenites of polyglycols, or their monoethers, by heating with arsenious oxide at 135° to 145°C. until the calculated amount of water separated. An inorganic acid catalyst (hydrogen chloride) may be employed. The arsenites may be used in conjunction with petroleum fractions as insecticides and wood preservatives.

A series of compounds, designated "hydrophilic lipins" have been prepared by partial esterification of polyglycols or glycerols, followed by sulphating.[86] The esters, which contain fatty acid and sulphate groups, are reported to be applicable as softening, wetting, emulsifying, detergent, frothing and penetrating agents. One such compound, the ammonium salt of lauryl diethylene glycol sulphate was made by dissolving monolauryl diethylene glycol in chloroform, and treating with chlorosulphonic acid dissolved in the same solvent. When all the acid had been added, the resulting mixture was aspirated with a dry, inert gas to remove hydrogen chloride, and ammonia gas was incorporated to furnish the ammonium salt. Among the uses suggested for compounds of this general class are included the preparation of cake-batter ingredients,[87] confections,[88] and cosmetic creams.[89]

Diethylene glycol has been suggested as an hygroscopic substance for tobacco.[90] It is reported that cigarettes prepared from such tobacco are less irritating when smoked than those containing either glycerol or devoid of any moistening agent. Experiments, conducted on patients who were apparently affected by glycerol-containing cigarettes, showed that there was some difference in the behavior of the two hygroscopic agents from this standpoint.

The dinitrate of diethylene glycol may be prepared by adding (at 10° to 15°C.) the glycol to a mixture containing water, nitric and sulphuric acids. The product may be used to decrease the sensitivity of glyceryl trinitrate to shock.[91] Polyglycol nitrates may be recovered from the spent acid by washing with the nitrate of another polyhydric alcohol, e.g., nitroglycerol.[92]

The propionates of such polyhydric compounds as di- and tri-ethylene glycol, may be incorporated in compositions containing cellulose ethers or esters.[93] On the other hand the ethyl[94] and butyl[95] ethers of diethylene glycol have been employed in liquids intended for the transmission of pressure. For example, such a liquid medium may contain 50 per cent castor oil, 25 per cent triacetin, and 25 per cent diethyleneglycol monobutyl ether. It has been suggested that the butyl ether of diethylene glycol may be used in conjunction with *o*-dichlorobenzene for dewaxing oils.[96]

PROPENE AND HIGHER GLYCOLS

Glycols containing more than 2 carbon atoms, which include 1,2-, 1,3- and other diols, have attracted considerably less interest than ethylene glycol. Propene glycol may be prepared by saponification of propene dichloride. Klebanskii and Dolgopol'skii[97] have found that heating 1,2-dichloropropane with aqueous sodium carbonate at 209°C. and 48 atm. pressure gave a yield of only 48 per cent. Using sodium bicarbonate and carrying out the reaction at 210°C. and 182 atm. pressure raised the yield to 60 or 65 per cent and gave 7 to 8 per cent of unsaturated compounds. The 1,2-glycol which was formed in these reactions was estimated by oxidation with potassium dichromate:

$$3CH_3CH(OH)CH_2OH + 4K_2Cr_2O_7 + 16H_2SO_4 \longrightarrow 3CH_3COOH + 3CO_2 + 4K_2SO_4 + 4Cr_2(SO_4)_3 + 22H_2O$$

Bowden and Adkins[98] observed the formation of propane-1,2-diol on hydrogenation of butyl lactate in the presence of a copper chromite catalyst at 250°C. and 150 to

200 atm. pressure. Another method of synthesis is hydrogenation of glycerol in the presence of a nickel-chromium oxide catalyst at 200°C. or higher and 2000 lbs. pressure.[99]

Schierholtz and Staples[100] have reported the physical properties of the propene and two of the butene glycols. 1,3-Butene glycol, since it could not be prepared from an olefin, was made in 75 per cent yield by the reduction of acetaldol with aluminum amalgam.

$$CH_3CH(OH)CH_2CHO + H_2 \longrightarrow CH_3CH(OH)CH_2CH_2OH$$

Some of the results obtained by Schierholtz and Staples are given in Table 118. The constants A and B for the vapor pressure equation:

$$\log_{10} p = B - \frac{A}{T}$$

which has been mentioned in connection with the properties of ethylene glycol are also given in the table.

TABLE 118.—*Physical Constants of Glycols.*

An interesting method for the synthesis of glycols by hydroxylation of olefinic bonds has been described by Milas and Sussman.[101] Employing *ter*-butyl alcohol these workers found that an anhydrous solution of hydrogen peroxide reacted with olefins in the presence of osmium tetroxide (dissolved in *ter*-butanol) to give glycols. For example, from 7 g. (0.1 mol.) of trimethylethylene (b.p. 38.3-38.4°C.), 48.4 cc. (0.1 mol.) of 7.03 per cent hydrogen peroxide reagent and 1 cc. of osmium tetroxide solution, reacted at room temperature for 24 hours, permitted the recovery of 2.9 g. of olefin and 2.3 g. (37.8 per cent yield) of a glycol. The product boiled at 175°C. and had a density of 0.992 at 25°. These values are in agreement with those given by Krassuski[102] (b.p. 176-8°, d_0^0 0.9893.) for the product which was prepared from trimethylethylene bromide and lead oxide. By their method, Milas and Sussman succeeded in synthesizing isobutene glycol, glycerol, phenyl-glyceric acid (from cinnamic acid), dihydroxybutyric acid (from crotonic acid), and *meso*- and *dl*-tartaric acids from maleic and fumaric acids, respectively.

The formation of butanediol-2,3 by fermentation of sucrose by *Aerobacter* has been studied by Kendall.[103] He found that yields corresponding to 50 per cent of the weight of sucrose used could be obtained by employing a medium containing 8 per cent sucrose, 0.175 per cent magnesium sulphate, 0.3 per cent or more of ammonium chloride, 0.175 per cent of disodium phosphate and a trace of calcium chloride. The optimum *p*H was 6.2.

Both *dl*-2,3-butanediol and *meso*-2,3-butanediol have been prepared by Wilson and Lucas.[103a] Their method comprised treatment of butene-2 with hypochlorous acid to secure the corresponding chlorohydrin, subjecting this to the action of potassium hydroxide to obtain the alkene oxide, and hydrating the latter with dilute aqueous perchloric acid. *cis*-Butene furnished the *dl*-compound and *trans*-butene the *meso*-derivative. Some of the physical properties of these two optically inactive glycols are given in Table 118A.

Boiling point (16 mm.)	89°C.	86°C.

Flavitzkii[104] has shown that the glycol prepared from amylene (obtained from amyl alcohol of fermentation) has the structure of isopropyl ethylene glycol. This was indicated by the formation of isobutyric acid on oxidation with sulphuric acid and potassium dichromate. According to Wiemann[105] oxidation of diprop-1-enyl ethylene glycol (4,5-dihydroxyoctadiene-2,6) results in the formation of a dimethyl hexitol (hexahydroxyoctane, m.p. 161-2°C.). Glycols are also said to be formed by the oxidation in acetic, propionic or butyric acid solution of olefins of 8 or more carbon atoms by hydrogen peroxide.[106] This result is in keeping with that reported by Milas and Sussman, mentioned previously in this chapter. For example, a 94 per cent yield of hexadecane-1,2-diol is said to be obtained from 224 g. of hexadecene-1 in solution in 100 g. acetic acid at 95°C. by oxidation with 170 cc. of 30 per cent hydrogen peroxide.

Edlund[107] has described the preparation of glycol ethers (which can be used as solvents) by reaction with an alcohol of an olefin oxide containing 4 or more carbon atoms. In this way 2-methoxy- and 2-ethoxy-1,1-dimethyl-ethanol (b.p. 142° and 147.8°C., respectively) were made from isobutene oxide and methanol or ethanol.

Reactions of the glycols of 3 or more carbon atoms parallel those of ethylene glycol. There is, for example, the possibility of forming esters and ethers, and of oxidation to carbonyl groups and finally complete oxidation of the molecule.[108] For example, oxidation of polyhydric alcohols to the corresponding carbonyl compounds may be brought about by the action of 1 mole of available oxygen on 2 carbinol groups in the presence of an activated copper catalyst at 270°C. In this way, biacetyl may be prepared from 2,3-butene glycol.[109]

Diols may be dehydrated at temperatures below their boiling point by the action of oxides of aluminum, zirconium or thorium.[110] For example, 1,12-octadecanediol may be converted into octadecenol by this procedure.

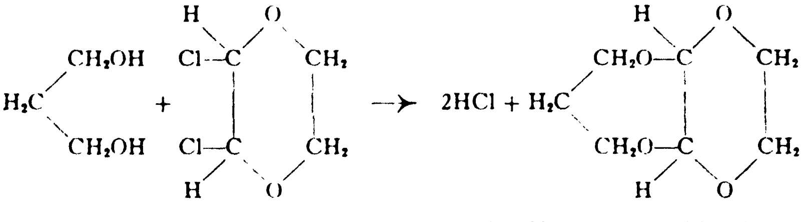
Lepkovsky and co-workers[111] have shown further that fatty acid esters of ethylene and diethylene glycol were toxic and caused enlargements and lesions in the kidneys of rats. On the other hand, the corresponding esters of propene glycol were nontoxic and produced good growth.

A rather interesting reaction of trimethylene glycol is that with 2,3-dichloro-1,4-dioxane which results in the formation of a cyclic ether:



Interaction occurs when the reactants are heated for 20 hours in boiling benzene.[112] The product is a mixture of two solid stereoisomers.

The action of *Aspergillus niger* (a mold) on propane-, butane-, pentane-, and hexane-1,2-diols has been investigated by Walti.[113] He showed that oxidation of the secondary alcohol group took place with the formation of a 1-hydroxyalkanone-2 except in the case of the hexanediol, which was unaffected. The products were optically active as were the unreacted glycols which were recovered.

The uses of 1,2- and 1,3-propene glycol parallel in some measure those of diethylene and ethylene glycol. For example, they have been used in amounts of 16 per cent of the water content of the product as preservatives for egg material when the latter is utilized in cosmetics.[113a] Trimethyleneglycol diacetate and various ethers and esters of the glycol have also been suggested as solvents for fluorodichloromethane when the latter is used as a refrigerant.[114]

Chapter 23

Production, Properties and Uses of Olefin Oxides and Their Derivatives

Of a variety of methods for the preparation of olefin oxides, the main ones fall into two groups:[1]

1. The action of alkalies, such as sodium hydroxide, on α-alkene halohydrins, by which the elements of hydrogen halide are removed.
2. The direct oxidation of olefins, reaction being carried out in the presence of a catalyst.

Insofar as known, large-scale operations involve only the first procedure, i.e., heating alkene chlorohydrins with alkalies, although there is considerable interest in the oxidation procedure. While it is doubtful if the latter method is being intensively employed technically at the present time, it is apparent that the trend is now definitely in that direction.

PRODUCTION OF OLEFIN OXIDES FROM CHLOROHYDRINS

Thole, Birch and Scott[2] recommend that a solution of ethylene chlorohydrin be added to somewhat more than the theoretical requirement of alkali (sodium hydroxide solution) at 10 to 20°C. The mixture is then allowed to react in a packed column at 35 to 50°C. under reduced pressure (90-105 mm.). Ethylene oxide is rapidly liberated and collected in a separate vessel as solid hydrate. A much shorter period of heating at higher temperatures is employed by Britton, Nutting and Petrie.[3] They suggest that substantially equimolecular proportions of alkene chlorohydrin and alkali hydroxide, carbonate or bicarbonate be heated under slightly superatmospheric pressure for a very short time. The period required is usually 5 to 60 seconds at temperatures between 90° and 150°C. By cooling rapidly to below 70°C. and distilling off the olefin oxide the formation of by-products is avoided. The method may be readily operated as a continuous process. Another procedure consists in passing vapor of the chlorohydrin, such as ethylene chlorohydrin or menthol chloride, over an active catalyst such as magnesium oxide, copper oxide, or a salt of either magnesium or copper.[4] The contact agent is more effective if mounted on a carrier.

Other chlorinated compounds besides the chlorohydrins have been found to yield ethylene oxide on treatment with alkalies. An example is β-chloroethyl acetate, which is said to give good results if sodium hydroxide is slowly added to it with constant stirring. The temperature of the mixture should be kept between the limits 40° and 150°C.[5]

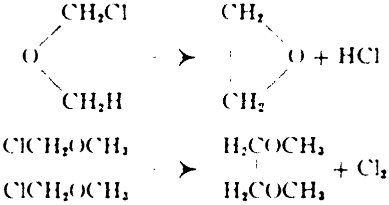
Dominik and Bartkiewiczówna[6] added an aqueous solution of ethyl hypochlorite drop-wise to calcium oxide or sodium hydroxide in a flask heated in an oil bath. A manometer was connected with a reflux condenser, and from the observed rise in pressure during the experiment, the yield of ethylene oxide was calculated. Better results were obtained with calcium oxide than with aqueous sodium hydroxide. The yield of ethylene oxide in the former case was as high as 90 per cent of the theoretical amount.

Another method,[7] applicable also for the preparation of cyclic and open chain ethers, consists in heating halogenated dialkyl ethers with finely divided metals. Copper, nickel and platinum have been found effective. Reactions in the liquid phase are carried out under 200 atmospheres pressure at temperatures between 50° and 100°C. Vapor-phase changes take place at temperatures from 100 to 250°C. When monochlorodimethyl ether is heated at 100°C. with metallic sodium, ethylene oxide is produced by removal of hydrogen chloride from one molecule of the chloro-compound. However, if two molecules of the ether are involved, only halogen is split off, and by condensation the dimethyl ether of ethylene glycol is formed.



Similarly, ethylene oxide and dioxane result from dichlorodiethyl ether using copper at 150°C. and 150 atmospheres pressure.

Olefin Oxides by Oxidation of Unsaturated Hydrocarbons

Francon[8] has reported a series of experiments on the preparation of ethylene oxide by direct oxidation of ethylene in the presence of an activated catalyst. The raw material, a gas mixture containing 92 per cent of ethylene, was produced by catalytic dehydration of ethanol. The results of Francon's tests are summarized as follows:

The optimum working temperature was found to be 375°C. and the most effective air-ethylene ratio was 10:1. Carbon dioxide was formed simultaneously with the oxide, but if water was introduced into the reaction mixture smaller yields of both products resulted, the oxide being affected less than carbon dioxide. The optimum gas flow, with a tube of 23 mm. internal diameter, was 80 liters per hour. At this rate, varying the proportions of air and ethylene reduced the formation of ethylene oxide and (to a less extent) increased that of carbon dioxide. At temperatures below 375°C. the production of ethylene oxide was lowered considerably, with practically no change in carbon dioxide yield. Above 375°C., however, both oxide and dioxide increased, the latter more than the former. Raising the pressure to 50 kg. per sq. cm. caused the development of more carbon dioxide at the expense of ethylene oxide, possibly because of partial combustion of the latter. Under optimum conditions, the production of carbon dioxide was attributed to direct oxidation of the ethylene gas.

---

[8] J. Francon, *Chim. et ind.*, 1933, **29**, (June Spec. No.), 869; *Chem. Abs.*, 1934, **28**, 465; *Brit. Chem. Abs.* **B**, 1933, 953.

According to Francon, industrial coke-oven gas may be used in this process if impurities, such as acetylene and compounds of sulphur and phosphorus, have been removed. These catalyst poisons may be eliminated by leading the raw gases through a purifier containing copper oxide maintained at temperatures of 150° to 200°C. For work on the commercial scale with treated coke-oven gases, an air-ethylene ratio of 1:3 is suggested, with a further supplement of about 5 per cent of pure oxygen. The gaseous mixture could then be conducted through a number of catalyst tubes in which the activity of the contact mass increased in the successive stages. Unchanged ethylene might be recycled, or hydrated to give ethyl alcohol.

Later, Francon[9] described the catalyst employed in his method. It was composed of silver or gold, or a mixture of the two, either as metals or as alloys containing small percentages of a third metal, such as copper or iron. It may be used in the form of fragments, thin sheets or flakes. An example is fine leaflets of silver containing a small amount of copper and gold.[10] These were made by rolling the alloy to form a foil, shredding the latter in a liquid medium, and finally drying and screening the metallic particles.

Admixtures of hydrogen, carbon dioxide and steam are permissible with the ethylene-oxygen reactants when the reaction temperature ranges from 150° to 400°C.

In a similar process for ethylene oxidation[11] the addition of water to the reaction mixture is said to minimize the formation of by-products, such as aldehydes. The catalysts recommended for this treatment are the metals antimony, lead, bismuth, silver, arsenic, nickel, tin, gold, copper, or iron. They may be used alone or as mixtures, or in admixture with their oxides. Hydrogen up to 5 per cent of the total volume of gases may be admitted. Temperatures between 150 and 400°C. and pressures up to 50 atmospheres may be employed. A typical reaction vessel consists of a silica tube containing a silver catalyst, or silver powder mounted on a carrier.

Several modifications of the above procedure have been disclosed. In one of these,[12] carbon dioxide is suggested as an alternative inert diluent, and pressures below atmospheric are recommended. The catalyst consists of silver activated by small amounts of either gold, copper or iron. As before, the reaction takes place at 150° to 400°C. in the presence of water. Another method[13] proposed by the same workers suggests employment of large proportions of carbon dioxide or nitrogen as diluent (at least 50 per cent by volume), and requires the complete absence of water. High temperatures, 300° to 400°C., and pressures up to 50 atmospheres, are employed. Contact agents consist of metallic silver, or silver containing small quantities of gold or copper.

Silver is the metal most generally recommended in the preparation of ethylene oxide from ethylene. It may be used in the form of wire, foil, or powder, or in colloidal suspension, either alone or with various metallic promoters. An active contact mass may be made by the decomposition of certain organic salts of silver, in particular the oxalate, by heating at 300°C.[14] As activators, the following metals are reported to be efficient: copper, gold, iron, manganese, cobalt, nickel, cerium, thorium and zinc. The most effective temperatures are said to be from 350° to 400°C. The gas mixture may carry steam, nitrogen or other diluent, and should contain 8 to 9 per cent by volume of ethylene.

The use of certain metallic compounds as catalysts for the oxidation of olefins to the corresponding oxides is advocated by Dreyfus.[15] The substances suggested are oxides of selenium, copper, silver, mercury, zinc, lead, antimony, arsenic and tellurium. Optimum conditions of temperature and pressure are given at 200° to 500°C. and above 10 atmospheres, respectively.

OLEFIN OXIDATIONS WITHOUT CATALYSTS

At high temperatures and in the absence of catalysts, the chief products of the oxidation of olefins are aldehydes and acids. For effecting the treatment in gaseous phase when it is desired to produce olefin oxides or glycols, temperatures from 250-600°C. are used.[16] The reaction vessel should be free from packing and have a surface-volume ratio of not over 4:1. The conversion period is longer than 10 seconds at 250-350°C. but only about 1 second at 450-600°C. Yields obtained in two instances were as follows: A 4:1 mixture of ethylene and oxygen, heated for 25 seconds at 315°C., gave 11.8 per cent ethylene oxide, 34.7 per cent formaldehyde and 6.9 per cent formic acid, the results being based on the amount of ethylene decomposed. A similar mixture of propene and oxygen held for 28 seconds at 270-360°C. produced propene oxide, propene glycol, propionaldehyde, propionic acid, acetic acid, formic acid, acetaldehyde and formaldehyde.

ETHYLENE OXIDE BY HYDROLYSIS OF ESTERS

Alkene oxides are formed by hydrolysis of volatile fatty esters having a double bond and a carboxyl group attached to the same carbon atom.[17] Ammonia or an organic base may be used to effect the reaction. For instance, a mixture of 5 parts of vinyl acetate, $CH_2{=}CHCO_2CH_3$, with 5 parts of pyridine and 1 part of water is heated to 100°C. in a vessel connected with a reflux condenser, the temperature of which is maintained at 20°C. Or, vapors of the vinyl ester (5 parts) and ammonia (1 part) may be passed through a silica-packed tube at 245-250°C. In either case, ethylene oxide is formed and may be separated by fractional distillation, the unchanged ester being first condensed by cooling to 20°C. and the oxide liquefied by further cooling.

BEHAVIOR OF ETHYLENE OXIDE

Properties of Ethylene Oxide. Ethylene oxide is a colorless, volatile liquid of $d_4^{?}$ 0.887. The pure substance boils at 10.7°C. It has a sweetish odor and mixes with water in all proportions. Its vapor forms explosive mixtures with air within very wide limits. The formation of binary mixtures as well as the boiling points of ethylene oxide-water or -alcohol admixtures were investigated by Kireev and Popov.[18]

Very little work appears to have been done on the physical properties of ethylene oxide, attention having been directed more to its physiological and chemical reactions. The valence angle of the oxygen in  is somewhat smaller than the corresponding figure for dimethyl ether, which has no bond connecting the two carbon atoms. The values, calculated from Raman frequencies, are 64° and 102°, respectively.[19]

Storage and Shipment. A method intended to minimize deterioration of ethylene oxide during storage and shipment has been recommended by Cox and Greer.[20] It consists in contacting the organic substance with cuprous oxide, manganese dioxide, alloys of iron, nickel and chromium, or metallic copper, aluminum, chromium, nickel, zinc or cadmium. The same treatment may be applied for the preservation of other alkene oxides, as well as dialkene oxides, aliphatic ethers with more than four carbon atoms per molecule, substituted derivatives of aliphatic ethers, alkoxy alcohols and their derivatives.

Thermal Decomposition of Ethylene Oxide. Travers[21] has made a study of the changes which take place during the thermal decomposition of ethylene oxide. He maintains that neither the mechanism nor the rate of the reactions involved can be satisfactorily followed by measuring the rate of the increase in pressure at constant volume. He considers that the reactions depend on the surface of the system and involve a chain mechanism. On the other hand, Thompson and Meissner,[22] summarizing measurements of the rate of decomposition of ethylene oxide over the range 435-505°C., find their results to agree, in general, with those of Heckert and Mack.[23] The latter workers decided that the thermal decomposition of gaseous ethylene oxide in a Pyrex container at 380-444°C. is a strictly homogeneous gas reaction, occurring in two steps with probably acetaldehyde formation as an intermediate step. There seemed to be an induction period. A decrease in the velocity of decomposition on the addition of inert gases was proportional to the pressure ratio of inert gas to ethylene oxide. The depressants included argon and neon (least effective), carbon dioxide, carbon monoxide, nitrogen, methane, ethane, propane, isobutane, helium. Hydrogen, on the other hand, increased the velocity of decomposition. However, Thompson and Meissner were unable to detect acetaldehyde among the products at any stage of the decomposition over the temperature range studied. The chief yields were carbon monoxide and methane with some formation of hydrogen and ethane. These workers found the velocity constant to vary with pressure over the range 15-800 mm. At 475°C. the period of half change was almost independent of initial pressure at above 250 mm. Between 250 and 40 mm. there was a bimolecular relation between the half change period and initial pressure and another such region below 40 mm. With initial pressures over 300 mm. the energy of activation was found to be about 54,000 cal. and at about 20 mm. approximately 50,000 cal.

Sickman[24] also reports that an induction period is exhibited in the pyrolysis of ethylene oxide and that the reaction is inhibited by the presence of inert gases. His results are in qualitative agreement with those of Heckert and Mack.[25] In a discussion of the various peculiarities of the ethylene-oxide pyrolysis, Fletcher[26] suggests the formation of free radicals and aldehydes at 400°C., followed by breaking up of the aldehydes, as an explanatory mechanism of the changes taking place. Fletcher found that at 443°C. acetaldehyde (exerting a pressure of 184 mm.) is half decomposed in 3 minutes in the presence of its isomer, ethylene oxide (partial pressure 17 mm.), whereas approximately 350 minutes were required with no ethylene oxide present. Later work by Travers and Seddon[27] points out the complexity of the changes involved in the thermal decomposition under consideration, in the case of both ethylene oxide and its isomer acetaldehyde. They found the latter, over a wide range of concentrations, to decompose mainly into methane and carbon dioxide at 360-500°C. in unpacked tubes, but into propene and carbon monoxide in packed tubes. However, some propene always appeared in the first case and underwent condensation producing 6-carbon and more complex hydrocarbons.

Echols and Pease[28] report confirmation of the observations of Heckert and Mack as to the cracking of *n*-butane, isobutane and propane in the presence of decomposing ethylene oxide at temperatures at which the normal decomposition of these paraffins is negligible. At a total pressure of about 500 mm. and a temperature of 425°C., the results given in Table 119 were obtained.

TABLE 119.—*Pyrolysis of Paraffins Admixed with Ethylene Oxide*

Hydrocarbon	Initial Ratio of Hydrocarbon to Ethylene Oxide	Ratio of Total Olefins to Carbon Monoxide
Ethane	1.6	<0.05
Propane	1.6	.55
Isobutane	1.7	.75
	1.6	1.2
n-Butane	4.1	4.5
	8.0	12.0

Echols and Pease point out the increase in the relative amount of olefin with the complexity of the paraffin and, in the case of *n*-butane, with the relative amount of the latter originally present. They report the rate of pressure increase as falling off rapidly on continued reaction, suggesting that products of paraffin decomposition are inhibiting reactivity. The effect of increases in temperature on the olefin-carbon monoxide ratio was not great. Other experiments were found to confirm the accelerated decomposition of acetaldehyde in the presence of ethylene oxide as reported by Fletcher and noted above.

Toxicity of Ethylene Oxide. Ethylene oxide is known to possess the properties of an efficient insecticide and fumigant. The toxicological activity of the compound has been investigated with reference to possible hazards involved in the handling of the material industrially.

Waite, Patty and Yant[29] tested the physiological effects of ethylene oxide on small animals. It was concluded that the toxic effects of ethylene oxide vapor are comparable with those of ammonia, being less dangerous than sulphur dioxide and hydrogen chloride, but more harmful than chloroform or carbon tetrachloride. In view of its distinct lachrymatory properties, at comparatively safe dilutions, however, this material may be said to give ample warning of its presence in the atmosphere before any serious harm can be done.

When used as a fumigant, ethylene oxide is frequently mixed with carbon dioxide, which increases its insecticidal value while decreasing its inflammability. A review of the work on the toxicity of ethylene oxide-carbon dioxide mixtures has been presented by Popov, Bezzub and Lebedeva.[30] The effect of added carbon dioxide gas on the toxic action of ethylene oxide is highest at the ratio of 1:10 to 1:15. The ignition safety limit of such mixtures is at 1:7.5 volumes. Aetox gas, an industrial product[31] containing ethylene oxide and carbon dioxide, is reported to be nearly ten times as toxic as the oxide alone. It cannot be used in the fumigation of wheat grain because of its destructive action on germinative power.

The effect of the vapor of ethylene oxide on insects has been studied by Hase.[32] A concentration of 60 g. per cubic meter was found to destroy insect eggs in 24 hours.[33] Horsfall[34] has described the action of ethylene oxide on the bean weevil and the flour beetle.

Determination of Ethylene Oxide. The use of ethylene oxide in the fumigation of foodstuffs has necessitated its accurate determination in air and gases as well as in the stored materials. A most useful method, which can be adapted for the analysis of both liquids and gases containing ethylene oxide, is that first suggested by Deckert[35] and later modified by Lubatti.[36] It consists essentially in allowing the oxide to react with a known amount of standard hydrochloric acid solution. Ethylene chlorohydrin is formed, and the excess acid is titrated. The absorbent liquid must contain a high concentration of halogen ions. Lubatti recommends a saturated solution of magnesium chloride, which he reports gives results which approach the theoretical much more closely than those obtained when sodium chloride is employed for this purpose. The equivalent of at least 300 g. of chlorine per liter of solution must be present, but in any case the best result obtainable corresponds to only about 94 per cent of the theoretical amount of ethylene oxide. Waite, Patty and Yant[37] used 2*N* hydrochloric acid and avoided hydrolysis of the ethylene chlorohydrin formed by titrating the excess acid against standard barium hydroxide solution. Lubatti, as well as Waite and his co-workers, employed methyl orange as indicator.

A micromethod of analysis of ethylene oxide-containing gases has been developed by Lubatti[38] and may be used in conjunction with the Page sampling apparatus.[39] The absorbent liquid consists of a solution of 490 to 540 g. of magnesium bromide per liter in 0.025 to 0.1*N* sulphuric acid. Such a solvent is said to allow 100 per cent recovery of ethylene oxide.

REACTIONS OF ETHYLENE OXIDE

Reactions with Water. Hydration of ethylene oxide in aqueous solutions containing 0.5 per cent sulphuric acid (as catalyst) has been investigated by Matignon, Moureu and Dode.[40] They found the products included the following glycols: ethylene glycol, b.p. 197°C. (97°C. at 14 mm.), d_4^{15} 1.1170 and n_D^{15} 1.4332; diethylene glycol, b.p. 244.5°C. (133°C. at 14 mm.), d_4^{15} 1.1197 and n_D^{15} 1.4488; triethylene glycol, b.p. 285°C. (165°C. at 14 mm.), d_4^{15} 1.1274 and n_D^{15} 1.4578, and tetraethylene glycol, b.p. 328°C. (198°C. at 14 mm.), d_4^{15} 1.1285 and n_D^{15} 1.4609. The relative proportions of these substances were considered to depend upon the ratio of ethylene oxide to water in the reaction mixtures and were only slightly changed by variations in reaction temperature (within the range 50-90°C.) or in acid concentration (within the limits 0.5 to 5.0 per cent sulphuric acid). The influence of ethylene oxide-water ratio on the proportions of products in a series of experiments carried out at 90-95°C. is shown in Table 120.

TABLE 120.—*Hydration of Ethylene Oxide at 90-95°C.*

Moles of Water Per One Mole of Ethylene Oxide	Per Cent of Individual Products on Ethylene Oxide Used Ethylene Glycol	Diethylene Glycol	Triethylene Glycol	Tetraethylene Glycol	Higher Glycols
10.5	82.3	12.7			
4.2	65.7	27.0	2.3		
2.1	47.2	34.5	13.0	0.3	
0.61	15.7	26.0	19.8	19.0	14.5

Reaction with Hydroxylated Organic Compounds. The action of ethylene oxide on the lower aliphatic alcohols forms the basis of a well-known method for the manufacture of glycol monoalkyl ethers.[41] The process may be effectively catalyzed by acidified hydrosilicates, such as aluminum hydrosilicate,[42] and also by fluorine compounds such as boron trifluoride. An 80 per cent yield of ethylene glycol monoisopropyl ether is said to be possible on heating isopropyl alcohol and ethylene oxide with boron trifluoride.[43] This type of reaction can, however, be carried out in the absence of catalysts by heating the reactants at a sufficiently high temperature.

In a process disclosed by Wittwer,[44] ethylene oxide and an alcohol such as ethanol are passed continuously through a reaction vessel heated to above 130°C. under sufficient pressure to maintain liquid-phase conditions. However, etherification does not stop at formation of simple glycol monoether, but, if sufficient ethylene oxide is present, monoethers of the higher glycols are formed by further condensation. Thus, combinations of aliphatic monohydric alcohols of more than 7 carbon atoms with 2 or 3 moles of ethylene oxide may occur at 120-160°C. in the presence of caustic soda or caustic potash. Yields consist of the corresponding ethers of di- and triethylene glycols. Such substances are reported to be of value in the textile, leather, paper, lacquer, pharmaceutical and cosmetic industries as wetting, emulsifying, penetrating and softening agents.[45] The monooleyl ether of triethylene glycol, prepared from oleyl alcohol and the requisite amount of ethylene oxide, is said to furnish stable aqueous emulsions of oils or fats. Polyolefin glycol ethers made by the action of olefin oxides on alcohols or on glycol monoethers are suggested as solvents for nitrocellulose and other cellulose esters.[46]

Zimakov and Churakov[47] recommend a 1:8 mixture of oxide and absolute alcohol heated in an autoclave with 1 per cent sulphuric acid for 7 to 8 hours at 100°C. The reaction period may be reduced to 3 hours by raising the temperature to 300°C. There was almost no formation of ethylene glycol or ethers of polyglycols. Yields of the monoethyl ether ranged from 95 to 99 per cent. On a commercial scale, using 95 per cent alcohol in 5:1 mixture with ethylene oxide and one-half of one per cent of acid catalyst the following products resulted from interaction at 150°C. for 5 hours: 35 to 40 per cent monoethyl ether of ethylene glycol, 55 to 60 per cent of ethylene glycol and 0.5 per cent mixed ethers. The dehydrating action of the ethylene oxide on the alcohol made possible the recovery of two-thirds of the alcohol in anhydrous form.

By the reaction of ethylene oxide with polyhydric alcohols, a wide variety of hydroxyethyl ethers may be readily prepared. A product, said to be useful as a dressing oil for cotton, may be obtained by heating diethylene glycol with 4 or more moles of ethylene oxide in the presence of nickel sulphate.[48] Hydroxy compounds resulting from condensation of alkene oxides with polyhydric alcohols may be esterified with higher aliphatic acids to furnish water-soluble esters useful as emulsifying agents in admixture with sulphonated higher aliphatic alcohols or their derivatives.[49] Some of the hydroxyethyl ethers of the higher polyhydric alcohols, such as pentaerythritol, sorbitol and hexitols, have been described by Schmidt and Meyer,[50] who recommend these substances and their esters as wetting, cleansing or dispersing agents in the textile industry.

The action of ethylene oxide on cellulose has been studied by Nikitin and Rudneva.[51] They found bleached cotton wool to react with ethylene oxide at 50°C. to yield a product containing only one hydroxyethyl group per 32 cellulose units of $C_6H_{10}O_5$. In the presence of dilute alkalies the degree of etherification was increased to 1 ether group per 4 to 8 cellulose units. A maximum etherification, namely, 1 ether per 1.5 cellulose units, was attained with 18 per cent caustic soda, or 35 per cent caustic potash, at 50-60°C. for 15 minutes. The products, which yielded solutions (in caustic soda) of increasing viscosity with the degree of etherification, were much more readily hydrolyzed and acetylated than cellulose.

Etherification of natural or artificial cellulosic textiles by alkene oxides in aqueous alkali of at least 11 per cent strength has been proposed by Lawrie, Reynolds and Piggott.[52] The type of finish obtained is determined by the oxide-cellulose unit ratio. For example, 0.3-1.0 mole of oxide produces an organdie, but 1-1.5 give a parchment appearance. Schorger[53] describes the manufacture of hydroxyalkyl ethers of cellulose by treating mercerized cellulose (freed from excess alkali lye by squeezing) with ethylene oxide, or other 1,2-oxides, or chlorohydrins, at below 45°C. With 11 to 20 per cent of ethylene oxide at 0°C. the products are soluble in 10 per cent aqueous alkali. Those obtained with less than 11 per cent of the oxide become soluble in this strength of alkali at about −20°C. although tending to form gels when the solution is warmed. Dreyfus[54] prepares hydroxyalkylcellulose by reacting an alkene oxide, or a chlorohydrin, with cellulose in the presence of a primary or secondary organic base containing at least one alkyl, aralkyl or alicyclic radical free from hydroxyl groups, such as diethylamine. Etherification of cellulose by means of gaseous alkene oxides at about 120°C. in the presence of weak acids or caustic alkalies or other basic substances, has also been suggested.[55] In another process proposed by Dreyfus,[56] cellulose is reacted with alkene oxides at pressures of at least 5 atmospheres and at temperatures such that the alkene oxide is either wholly liquid or partially or wholly gaseous, to yield hydroxyalkyl ethers for use as sizes, dressings and finishes for textiles. Etherification of partially esterified cellulose by alkene oxides in the absence of strong inorganic bases and under conditions such that no substantial saponification occurs, has also been suggested.[57]

Hydroxyethyl-lignin has been obtained by Nikitin and Rudneva[58] as an amorphous solid having greater hygroscopicity and swelling capacity than lignin. The product was made by treating Willstatter lignin[58a] with ethylene oxide and 18 per cent aqueous caustic soda at 70°C. for 24 hours, for 2 hours at 70-72°C. or for 2 days at room temperature. The crude lignin ether was then separated by means of water, washed with alcohol and ethyl ether and finally dried. On hydrolysis for 5 hours with 5 per cent sulphuric acid a pure lignin hydroxyethyl ether was obtained. It is an amorphous, insoluble material, having 38.76 per cent of the group $—OCH_2CH_2OH$ and 5.18 per cent of HO— group that may be acetylated. The former group may be removed by hydrogen iodide at 135-140°C., but is not affected by boiling with 5 per cent sulphuric acid. Such behavior is considered due to presence of a simple ether bond. It was believed that lignin reacted with ethylene oxide as indicated in the following scheme suggested by Shoruigin and Ruimashevskaya.[59]

$$R—OH + (CH_2)_2O \longrightarrow R—O—CH_2—CH_2—OH$$

Reaction with Hydrogen Halides and Metallic Halides. Ethylene oxide combines energetically with hydrogen chloride, even in aqueous solution.

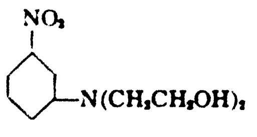
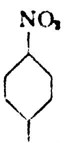
with the formation of ethylene chlorohydrin. Preparation of the latter from the oxide and liquid hydrogen chloride has been described by Gebauer-Fuelnegg and Moffett.[60] Thus, hydrogen chloride present as impurity in tetraethyl silicate preparations[61] may be removed by addition of the alkene oxide.

It has long been known that aqueous solutions of certain metallic chlorides, such as those of zinc, manganese and magnesium, are decomposed by ethylene oxide with the formation of ethylene chlorohydrin and a precipitate of the metallic hydroxide or oxychloride. This reaction has been utilized by Ziese[62] for the preparation of sols and reversible gels of hydrated metallic oxides. For example, addition of ethylene oxide to aluminum chloride in aqueous solution yields ethylene chlorohydrin and aluminum hydroxide. The latter remains as a sol until about 90 per cent of the theoretical amount of ethylene oxide has been added, after which solidification to a clear gel occurs. By-products can be removed from the sol by extraction with solvents (for the chlorohydrin) or by distillation. The sols obtained from solutions of aluminum, chromium, zinc and thorium halides, which may be regarded as containing highly basic salts, may be dried to reversible gels; the latter can be again converted into stable sols when contacted with water, ethyl alcohol or glycerol. The metal oxide hydrates are precipitated as gels, without passage through a hydrosol phase, by the use of ethylene oxide in excess. In the case of bivalent metals, such as zinc or manganese, precipitation often occurs in the presence of quite small amounts of ethylene oxide owing to the instability of the sol phase. Bromides and iodides can be used in place of chlorides; propene oxide instead of ethylene oxide. Water may be replaced by 96 per cent ethyl alcohol.

Reaction with Organic Bases. Ethylene oxide reacts readily with a large number of primary and secondary organic bases with the production of the corresponding hydroxyethylamine. Thus, by heating equimolecular proportions of dibenzylamine, water and ethylene oxide in a sealed tube at 100°C., Gabel[63] obtained a 25 per cent yield of β-dibenzylaminoethyl alcohol, m.p. 45.5-47°C. Under similar conditions the alkene oxide and water (1 mole each) react with *m*-phenylenediamine at 30°C. to give after 8 hours a 31 per cent yield of β-*p*-aminophenylaminoethyl alcohol, $HOCH_2CH_2NHC_6H_4NH_2$, m.p. 52-53°C.[64] The compound is soluble in alcohol, acetone and water, but less so in ethyl ether and benzene. On standing it resinifies. It is said[65] that nitroarylamines, on heating with 2 molecular proportions of ethylene oxide at 140-170°C., are converted into their NN-di-β-hydroxyethyl derivatives. Similar derivatives of *m*-nitroaniline and *p*-nitroaniline have constitutions represented by the following formulas:



m.p. 98-99°C.



m.p. 101-102°C.

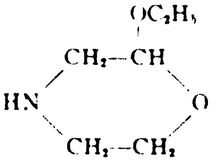
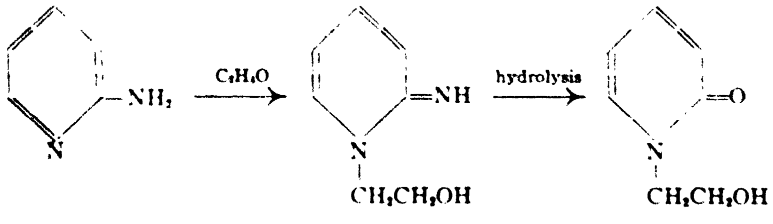
Secondary aromatic bases of the type of β,γ-dihydroxypropylaniline,[66] or their γ-alkyl ethers,[67] may be converted into the corresponding N-β-hydroxyethyl derivatives by heating with ethylene oxide under pressure at about 150-160°C. Ruberg and Shriner[68] have described the condensation of a number of aliphatic secondary amines with ethylene oxide at below 60°C. to yield mixtures of alcohols of the types $NR_2CH_2CH_2OH$ and $NR_2(CH_2CH_2O)_nH$, in which R is an aliphatic radical. These can be reacted with nitrobenzoyl chloride to give the corresponding nitrobenzoates which in turn may be reduced to the respective aminobenzoates. The latter have possible applications as local anesthetics. It was noted, however, that although this property increased with the molecular weights of the substances, nevertheless their toxicity also became greater.

In the absence of water many of the well-known reactions of ethylene oxide with the simple primary and secondary bases do not take place at all or only very slowly. Knorr[69] has shown, for example, that ethylene oxide does not react with carefully dried 2-aminoacetaldehyde. In the presence of water, however, complete combination occurs and the product, on standing, loses water with the formation of a substance (b.p. 253°C.) which is probably 5-ethoxymorpholine,



Nearly theoretical yields of tertiary alkylolarylamines are said[70] to be obtained by heating a secondary alkylarylamine with an alkene oxide in a closed vessel at 140-150°C. The products exemplified by 1-(phenylethylol)-butane may be used as dye intermediates.

An unusual rearrangement occurs during the condensation of 2-aminopyridine and dry ethylene oxide in methyl alcohol at 15-20°C. Under these conditions the formation of 1-β-hydroxyethylpyridoneimine takes place.[71] This substance may be readily hydrolyzed to the corresponding pyridone compound by boiling with 10 per cent caustic soda solution. The changes may be indicated thus:



Natural polymeric aliphatic amino compounds, such as casein, horn, wool, glue or albuminous materials, may be reacted with ethylene or propene oxide in a slightly alkaline aqueous medium.[72] Such alkoxy derivatives are not decomposed by fermentation and may be used for emulsifying fats and waxes. They may be reduced by catalytic hydrogenation. In another procedure, casein is treated in aqueous suspension (neutral or weakly acidic with acetic or other organic acids) at 40-90°C. with an alkene oxide. The products are insoluble in water and weak aqueous alkalies but soluble in dilute acids. They may be used as adhesives, sizing and finishing agents and for molding.[73]

An interesting development in the reaction between alkene oxides and organic nitrogen compounds is the observation that carboxyl- or sulphonamides, with at least one replaceable hydrogen atom and a radical of at least 8 carbon atoms, may undergo condensation with up to 3 moles of an oxide for each replaceable hydrogen atom, in the presence of an alkaline catalyst. For example, dibutylnaphthalenesulphonamide reacts with ethylene oxide to yield a product having dispersing, emulsifying and wetting properties. Moreover, the products obtained may form with polybasic acids combinations having acid functions.[74] Combination of ethylene oxide, either alone or in non-hydroxylic media, with a primary, secondary or tertiary water-soluble amine or with a primary or secondary acylated water-soluble amine having at least two hydroxyl groups, has also been described.[75] Such materials are suggested as wetting and other agents for use in the treatment of textiles. Similar auxiliary agents are prepared by heating ethylene oxide with the condensation products of polyhydroxylated primary or secondary aliphatic amines (such as methyl glucamine) and higher aliphatic acids.[76]

Polymerization of Ethylene Oxide. Ethylene oxide (and propene oxide) undergo polymerization beyond the dimer stage when subjected to the action of caustic potash or other alkali or alkaline-earth metal compounds in the presence of an inert organic liquid medium. In most instances temperatures of 110-130°C. have been found effective.[77] Polymers of ethylene or propene oxide may be employed as the liquid if in a low degree of polymerization. The latter undergo further condensation so that a homogeneous product is formed.[78]

By the slow polymerization of ethylene oxide at ordinary temperature under the influence of strontium, calcium and zinc oxides, or carbonates, Staudinger and Lohmann[79] prepared eucolloidal products having mean molecular weights of 100,000 or over, whereas previous experiments with other catalysts had yielded polymers of molecular weight not exceeding 12,000. Sluggish action is necessary for this change, the type of transformation depending on the catalyst. Oxides of iron, magnesium and lead, as well as silica gel and carbon, were without effect, but alumina slowly yielded hemicolloids. Best results followed use of zinc oxide, which was easily removed without affecting the products. All polyethylene oxides were crystalline. A "meandering" form of the molecule has been postulated which explains the solubility and low melting points of the compounds in contrast with the polyoxymethylenes and the paraffins.[80]

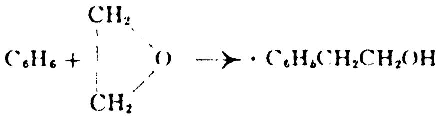
[80] For a discussion of the structure of ethylene oxide polymers, see Carleton Ellis, "The Chemistry of Synthetic Resins," Reinhold Publishing Corp., New York, 1935, 990.

The structure of the polyethylene oxides has been investigated by Sauter,[81] using x-ray methods.

Reaction with Aromatic Hydrocarbons. In the presence of appropriate catalysts, ethylene oxide may be condensed with aromatic hydrocarbons to give the corresponding β-arylethyl alcohols, usually in poor yield. In the case of benzene, the product is phenylethyl alcohol (phenethyl alcohol). The reaction may be represented as follows:



$$C_6H_6 + \begin{array}{l} CH_2 \\ | \quad \rangle O \\ CH_2 \end{array} \longrightarrow C_6H_5CH_2CH_2OH$$

Condensation of alkene oxides with hydrocarbons such as benzene in the presence of a Friedel-Crafts catalyst, a non-substituted heterocyclic compound (e.g., pyridine or quinoline) or a monohalogen derivative such as monochlorobenzene, at temperatures up to 100°C., has been suggested by Hopff.[82] In making phenethyl alcohol, the temperature is best maintained at 5°C. Further details of the influence of temperature on the condensation of ethylene oxide with benzene in the presence of aluminum chloride or ferric chloride are given by Klipstein.[83] The latter states that bibenzyl, which is produced at the higher operating temperatures, is formed only to a negligible extent at temperatures of about 5-6°C., when the yield of phenethyl alcohol amounts to 65 per cent of the theoretical. Low temperatures (0 to 10°C.) are recommended also by Theimer.[84] Carpenter[85] proposes to employ an acid-condensing agent (aluminum chloride) in an amount at least 3 to 4 times that of the aliphatic oxide used. He further provides for removal of hydrogen chloride in a stream of air or inert gas.

According to Valik and Valik,[86] loss of ethylene oxide as chlorohydrin can be minimized by diluting the gaseous oxide with an inert diluent such as air, nitrogen or carbon dioxide. The process may then be carried out at 5-10°C. in the presence of ammonia or an amine, such as triethanolamine, to take up the free hydrogen chloride.

Alkene oxides may be converted into aralkyl alcohols by reaction with metal compounds of certain aromatic hydrocarbons.[87] Thus, combination of ethylene oxide with phenyl sodium in toluene suspension at −50°C. gives phenethyl alcohol. β-*p*-Tolylethyl alcohol (b.p. 113-117°C. at 11 mm.) is produced in a similar manner from *p*-tolyl sodium.

Reaction with Hydrogen Sulphide and Mercaptans. Chichibabin and Bestuzhev[88] observed that combination of equimolecular proportions of ethylene oxide and hydrogen sulphide takes place slowly in aqueous solution at 8-10°C. After 10 days a quantitative yield of thioethylene glycol, b.p. 54°C. at 12 mm., was obtained. With twice as much of the oxide in a cooled dilute solution, the product was thiodiethylene glycol, b.p. 130°C. at 2 mm. A mixture of viscous polyglycol sulphides resulted in the absence of cooling. With 3 moles of ethylene oxide in dilute solution, hydrogen sulphide combined to give the strongly basic triethylolsulphonium hydroxide. These reactions, which are catalyzed by mineral acids, chlorides of aluminum or heavy metals, may be represented by the scheme:

The production of thiomono- and thiodiethylene glycols and triethylolsulphonium hydrate by direct combination of hydrogen sulphide and ethylene oxide at different temperatures and pressures has been previously reported by Chichibabin.[89] In this case the reaction was said to be favored by the presence of water, lower alcohols and catalysts such as porous clay or alumina.

Thiodiethylene glycol in 90 per cent yield was secured by Nenitzescu and Scarlatescu[90] on passage of a gaseous mixture of 1 mole hydrogen sulphide and 2 moles ethylene oxide through glass beads moistened with the product of reaction. Replacement of the hydrogen sulphide by mercaptans led to formation of the corresponding hydroxyethyl thioethers in good yields. The formulas and properties of some of these substances prepared by Nenitzescu and Scarlatescu are given in Table 121.

TABLE 121.—*Hydroxyethyl Thioethers.*

Oxide Used	Mercaptan	Formula of Product	Boiling Point
Ethylene oxide	Ethyl	$C_2H_5SCH_2CH_2OH$	--
" "	Phenyl	$C_6H_5SCH_2CH_2OH$	119-120°C. at 4 mm.
Cyclohexene oxide	Propyl	$C_3H_7SC_6H_{10}OH$	96- 97°C. at 3 mm.
" "	Phenyl	$C_6H_5SC_6H_{10}OH$	148-149°C. at 4 mm.
" "	Benzyl	$C_6H_5CH_2SC_6H_{10}OH$	158-160°C. at 3 mm.

It has been proposed[91] to condense mercaptans (except those containing the —SH group linked to >CO or a heterocyclic nucleus) with alkene oxides, such as ethylene oxide. It was suggested that groups introduced have at least one ether oxygen atom and not less than 4 carbon atoms. The products are soluble in water and are said to be scouring, dispersing, wetting and emulsifying agents. As an example, dodecyl mercaptan is heated with 5 equivalents of ethylene oxide at 140°C. in the presence of 0.5 per cent of sodium methoxide.

Substitution of inorganic sulphur-containing compounds for mercaptans is reported to furnish thioethers.[92] An example of this is the preparation of diethyl sulphide (b.p. 55-56°C.) from ethylene oxide and potassium thiocyanate. The latter may be replaced by thiourea.

Miscellaneous Reactions. With Grignard reagents, ethylene oxide has been shown to combine with the formation of the corresponding hydroxyethyl derivative according to the equation,

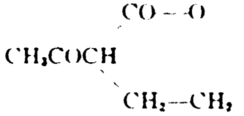
in which R is an alkyl or aryl radical and X is a halogen. For example, it is proposed[93] to synthesize phenethyl alcohol by reacting phenylmagnesium chloride (obtained by heating chlorobenzene with magnesium at 150-160°C. in the absence of a solvent) with ethylene oxide (or chlorohydrin) in the presence of benzene. This type of reaction has been particularly useful in the preparation of certain acetylenic alcohols by reacting ethylene oxide with the Grignard compounds of monoalkylacetylenes. Faucounau[94] made 3-nonyn-1-ol and 3-decyn-1-ol by this procedure.[95] In this manner 3-octyn-1-ol was obtained by Danehy, Vogt and Nieuwland[96] from hexyne-1 and ethylene oxide. Condensation of 2 moles of the Grignard reagent of heptyne-1 with 1 mole of ethylene oxide was found to yield ethylene bromohydrin and 3-nonyn-1-ol in addition to some unchanged heptyne-1. A similar reaction occurred with the Grignard reagents from phenylacetylene.[97] Bachman[98] calls attention to "the fact that this type of reaction was first reported by Iotsitch[99] who used it to prepare 3-pentyn-1-ol."

Knunyantz, Chelintzev and Osetrova[100] have observed that ethylene oxide combines readily with ethyl sodioacetoacetate in ethyl alcohol solution at 0°C. The product, after decomposition with dilute acetic acid, is 1-aceto-3-butyrolactone,



This compound can be hydrolyzed by warm 5 per cent hydrochloric acid to produce 3-keto-*n*-pentanol-1. Addition of sodium bisulphite to ethylene oxide was accomplished by Lauer and Hill.[100a] The product is reported to be sodium β-hydroxyethanesulphonate, a colorless crystalline compound which melts at 192-194°C.

Uses of Ethylene Oxide

Although the principal application of ethylene oxide is that of a chemical intermediate in the manufacture of solvents such as glycol ethers, the compound itself is widely used as an insecticidal fumigant, particularly in the preservation of stored grain. As employed in fumigation, the oxide is usually admixed with an excess of carbon dioxide, a liquid mixture of 1 part of ethylene oxide and 9 parts of carbon dioxide being marketed for this purpose. For the destruction of insects, Brown[101] recommends the following minimum lethal concentrations per 1000 cu. ft. of room space: 5 lbs. for 3 hours, 3 lbs. for 6 hours, 2 lbs. for 18 hours or 24 hours. The influence of various factors on the efficiency of fumigation by ethylene oxide-carbon dioxide mixtures has been studied by Twinn,[102] who found that this gas penetrated many containers, except boxes wrapped in three layers of Cellophane. In comparing the fumigant with a mixture of ethylene dichloride and carbon tetrachloride, the latter was found to penetrate less readily and to be less agreeable to handle, although it exerted no ill effects on workers even when inhaled in considerable amounts. The advisability and advantages of adding carbon dioxide to ethylene oxide used as a disinfectant of vegetable materials (particularly grain), under partial vacuum or at atmospheric pressure, have been discussed by Lepigre.[103]

In the fumigation of ships and warehouses, the method of vaporization of the liquid fumigant requires careful consideration. This question has been discussed by Page and Lubatti,[104] who recommend that the latent heat requirements of such vaporization should be supplied from an external source. These investigators have described a vaporizer for use in fumigating dried fruit in barges and in similar operations. The effect of ethylene oxide on books and writing papers has been studied by Weber, Shaw and Back.[105] Their tests indicated that this oxide may be used with safety.

Cotton and Young[106] have described the use of solid carbon dioxide and ethylene oxide, carbon disulphide or other fumigants in the treatment of seeds, bulbs and foods for their protection against certain insects. A wet or dry preserving agent, for fruit-trees, vines or cereals, has been suggested by Pfaff and Erlenbach. It was made by treating a solution of cupric chloride with an alkene oxide and removing excess of the latter.[107]

Other proposed uses for ethylene oxide are in the stabilization of aliphatic nitrates (in conjunction with acetone)[108] in the treatment of leguminous vegetable materials for the destruction of their bitter principles[109] and for reducing the nicotine content of tobacco.[110] A liquefied mixture of 5 parts of ethylene oxide and 1 part of methyl alcohol has been suggested[111] as a fuel for portable lighting devices, such as cigarette lighters, the fuel being burned in gaseous form without the employment of a wick.

Emulsifying and dispersing agents may be produced by the action of ethylene oxide on the partially oxidized marine-animal oils that result from the oil-tanning of skins.[112]

ETHANOLAMINES

Alkene oxides combine with ammonia and with primary or secondary organic bases with the formation of hydroxyalkylamines or alkylolamines. The three main products of the reaction between ethylene oxide and ammonia, in aqueous solution, are:

Monoethanolamine	$NH_2CH_2CH_2OH$
Diethanolamine	$NH(CH_2CH_2OH)_2$
Triethanolamine	$N(CH_2CH_2OH)_3$

This addition, however, does not necessarily end with the formation of triethanolamine, since the hydroxyl groups of the latter compound can undergo further reaction with ethylene oxide to yield complex hydroxyethyl ethers of triethanolamine.[113] In general, all three of the simple ethanolamines are obtained simultaneously by reaction of ethylene oxide with strong aqueous ammonia, a large excess of ammonia tending to favor formation of monoethanolamine. However, triethanolamine is the main product when approximately equimolar proportions of ethylene oxide and ammonia are used.

Kautter[114] proposes to treat 1 mole of ethylene oxide with 1 to at least 20 of ammonia, the reaction being carried out at elevated temperatures and pressures, if necessary. Thus, an 83.2 per cent yield of monoethanolamine is prepared by heating a mixture of 88 g. of ethylene oxide and 6 liters of 18.3 per cent aqueous ammonia at 94°C. for 1 hour, the pressure being about 36 lb. per sq. in. At the end of this period, excess ammonia is removed by release of pressure and absorbed in water. The residual liquid is distilled to recover the monoethanolamine. An apparatus for effecting the production of ethanolamines has been described by Reid and Lewis.[115] It consists of porous tubes through which ethylene oxide is passed into aqueous ammonia. The latter is continuously circulated through a heat exchanger to maintain a reaction temperature of 40-50°C. Excess of ammonia and water may be separated by distillation, leaving a residue of triethanolamine that contains 25 to 35 per cent of diethanolamine.

In experiments carried out on a semi-commercial scale, Kedrinskii and Plaska[116] fed ethylene oxide and ammonia in stoichiometrical proportions into a reacting zone filled with a solvent medium. Compressed air was utilized to force the mixture through the solvent, an oxide velocity of 320 g. per liter of solvent being maintained at a temperature of 60°C. The final product consisted of 1.5 per cent di-, 75 per cent triethanolamine and 13 per cent polymerized material with traces of the monoamine and nearly 10 per cent of water. The yield amounted to 1008 g. per 1000 g. ethylene oxide or 89 per cent of theory.

Pure triethanolamine has been recovered from the technical product in the following manner by Germann and Knight.[117] The crude material is first acidified with a slight excess of concentrated hydrochloric acid at 10-15°C. After standing for 1 hour, 70 per cent of the pure hydrochloride separates out and can be filtered, washed with ethyl alcohol (or isopropyl alcohol) and decomposed with caustic soda in isopropyl alcohol solution. The base recovered by vacuum distillation, b.p. 194-195°C. at 10 mm. and d_{20}^{20} 1.1239, is 99 per cent triethanolamine. The solubility of its hydrochloride in isopropyl and ethyl alcohols at 65°C. is 1.1 and 3 g. per liter, respectively .

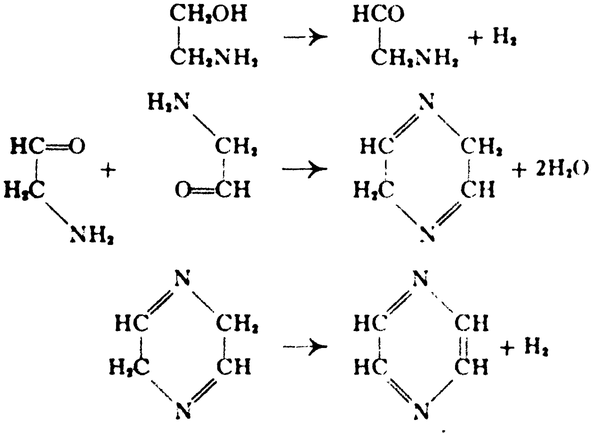
Properties of Ethanolamines. The ethanolamines are weak bases and yield readily hydrolyzable salts with many weak acids. In other chemical properties, however, they exhibit important differences.

When monoethanolamine is heated with diethyl sulphate, at temperatures not over 200°C., the hydrogen atoms of the amino-group are displaced by ethyl radicals, with the formation of diethylaminoethanol.[118] The method is applicable for the production of other dialkylamino alcohols.

Monoethanolamine and similar aliphatic amines have been found to function as catalysts for the production of ethers of the polyalkene glycols by the action of alkene oxides on polyhydroxy alcohol derivatives.[119] For example, the monoethyl ether of triethylene glycol is formed by treating the corresponding diethylene compound with ethylene oxide.

Monoethanolamine vapor undergoes partial dehydrogenation and condensation in contact with dehydrogenating catalysts, such as finely divided copper or zinc oxide·(containing 4.5 per cent sodium carbonate), at 300°C. In this way Aston, Peterson and Holowchak[120] obtained a 5.6 per cent yield of pyrazine, a cyclic base, b.p. 112-114°C. at 730 mm., evidently produced in the following way:



pyrazine

The gas collected in the runs with the reduced copper activator was exclusively hydrogen. The yield of pyrazine was isolated as the mercuric chloride double salt, $C_4H_4N_2 \cdot HgCl_2$. The catalyst was eventually rendered inactive by resins which Aston and his associates thought were formed by side reactions from the amino-acetaldehyde. In the absence of a catalytic medium the ethanolamine was quite stable at 300°C. Another base, namely, ethylenimine, C_2H_4NH, b.p. 55-56.5°C., can be prepared by heating the acid sulphate of monoethanolamine to 250°C. and subsequently distilling the resulting product with 40 per cent caustic soda.[121]

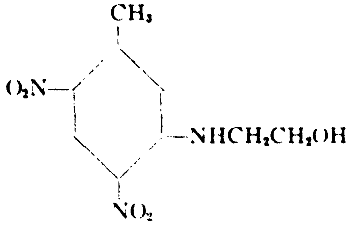
under pressure) of higher homologues of ethylene oxide with a (β,γ-dihydroxypropyl)- or a (γ-alkoxy-β-hydroxypropyl)-aminobenzene.[128]

Monoethanolamine reacts with 2,4,5-trinitrotoluene to form a substitution product, 4,6-dinitro-3-ethyloltoluidine, m.p. 115°C., one nitro group being eliminated from the aromatic nucleus during reaction. On the other hand, di- and triethanolamines do not undergo a similar condensation but yield addition compounds with trinitrotoluene.[129]



Under the influence of heat any one of the ethanolamines may function as a reducing agent, the reaction being said to depend on the decomposition of the amino-alcohol into ammonia and an aldehyde. The reduction of anthraquinone, azobenzene and acetone to anthranol, aniline and isopropyl alcohol, respectively, under the influence of ethanolamines has been studied by Meltsner, Wohlberg and Kleiner.[130] It was found that the ethanolamines would also reduce aqueous solutions of certain metallic salts, e.g., those of silver, lead and mercury.

The hydroxyl group, or groups, in the ethanolamines may be replaced by chlorine on reaction with thionyl chloride. The method has been employed by Ward[131] for the preparation of the derived chloroethylamines. It was found that the chlorine atoms in these compounds were highly reactive and that β,β',β''-trichlorotriethylamine exhibited a powerful vesicant action as did its hydrochloride. The corresponding primary and secondary compounds had no such action.

Reaction with Inorganic Salts. The ethanolamines are sharply differentiated in their reactions with certain inorganic salts.[132] All will react with cobalt chloride (and certain other bivalent metal salts), in absolute ethyl alcohol solution, to furnish simple addition products. But only the tertiary base yields definite compounds in aqueous solution, under which circumstance the primary and secondary bases give rise to indefinite mixtures of hydroxides and basic cobalt salts. This difference in behavior in aqueous solution has been ascribed by Tettamanzi[133] to the lower basicity of triethanolamine as evinced by the lower *p*H values of its 0.1*M* aqueous solutions. Hieber and Levy[134] have described a large number of double compounds of mono-, di- and triethanolamine with cobalt, nickel, copper and zinc salts.

In the reaction between triethanolamine and metallic salts in aqueous solution, several different types of combination have been found to occur. The interaction of triethanolamine with aqueous salts of nickel, cadmium, calcium, strontium and magnesium was found by Tettamanzi and Carli[135] to result in the formation of double compounds of the type $MCl_2 \cdot 2$(triethanolamine), in which the metal is probably coordinated through the oxygen of the hydroxyl groups or the nitrogen atoms. On the other hand, the effect of triethanolamine on aqueous solutions of cobalt chloride, cobalt bromide, cobalt thiocyanate, copper thiocyanate, zinc chloride, zinc sulphate and cadmium chloride has been found by Garelli and Tettamanzi[136] to involve double decomposition with the formation of mixed halide alcoholates in which one or more metal atoms replace the hydrogen atoms of the hydroxyl groups of the tertiary base. This type of reaction is exemplified by the combination of hydrated triethanolamine with cobalt chloride according to the equations:

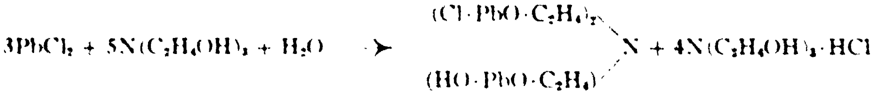
$$(HOCH_2CH_2)_3N + H_2O + CoCl_2 \longrightarrow Co(OH)Cl + (HOCH_2CH_2)_3NHCl$$
$$Co(OH)Cl + (HOCH_2CH_2)_3N \longrightarrow ClCoOC_2H_4N(CH_2CH_2OH)_2 + H_2O$$

Similar compounds, in which the triethanolamine behaves as an ammonium base, have been obtained with certain salts of beryllium and lead and also with nickel iodide. Further studies of these complexes of triethanolamine with aqueous solutions of metallic salts have been contributed by Garelli[137] and by Tettamanzi and Carli.[138]

Garelli[139] also studied the combinations occurring on addition of triethanolamine to concentrated solutions of metallic salts in water. In case of nickel, calcium, strontium and magnesium chlorides, double salts resulted, taking the form of colored crystals, e.g., $CaCl_2 \cdot 2N(C_2H_4OH)_3$. Similar compounds were obtained with nickel bromide and nitrate, cobalt iodide, lead acetate and the sulphates of nickel, cadmium and copper. On the other hand, with lead chloride and some other salts, hydrogen atoms of the hydroxyl groups were substituted, as may be indicated in the reaction



$$3PbCl_2 + 5N(C_2H_4OH)_3 + H_2O \longrightarrow \begin{matrix} (Cl \cdot PbO \cdot C_2H_4)_2 \\ \\ (HO \cdot PbO \cdot C_2H_4) \end{matrix} \!\!> N + 4N(C_2H_4OH)_3 \cdot HCl$$

In this connection, it is interesting to note that Brockman and Nowlen[140] have obtained good electrodeposition of both nickel and cobalt from solutions of these metals containing either an excess of triethanolamine or just enough to give a clear solution. From similar solutions of cobalt sulphate-triethanolamine it was also possible to plate the metal successfully on copper, steel, nickel and zinc with cathode efficiencies as high as 98 per cent. Alloys of nickel and cobalt have also been deposited from triethanolamine solutions of these metals.[141] They contained nickel chloride and sulphate, cobalt sulphate and some sodium sulphate. The concentrations of nickel and cobalt may vary over a wide range; the current densities ran from 3.4 to 15.5 amperes per square decimeter.

Double compounds of triethanolamine with calcium chloride, iodide and bromide and also with sodium iodide, potassium iodide and lithium chloride as well as a compound of diethanolamine with calcium bromide have been reported[142] for use in the dissolution of acid products, such as barbituric acids, in aqueous media.

Raymond[143] has observed that, whereas both nickel and cobalt form soluble complex compounds with triethanolamine in the presence of excess aqueous caustic soda, the nickel complex is quantitatively decomposed on boiling, that of cobalt being stable. A quantitative separation of nickel from cobalt, by precipitation of nickel hydroxide, is said to be possible by this procedure.

When an ammoniacal aqueous solution of nickel sulphate is added to a solution of triethanolamine containing caustic potash, a green color is obtained even in the presence of 1 part per 5000 of triethanolamine. This coloration is said by Jaffe[144] to be specific and to be capable of use in the colorimetric estimation of either nickel or triethanolamine. According to Simon,[145] the formation of a purple coloration when solutions of triethanolamine (made alkaline with ammonia) are treated with cobalt chloride, is not sufficiently characteristic or sensitive for the detection of the tri-amine in toilet preparations.

For the determination of triethanolamine in toilet creams and emulsions, Fleck[146] precipitates it as the hydroiodide, $(CH_2OHCH_2)_3N \cdot HI$, m.p. 169°C., which contains 53.6 per cent of the base. On weighing the compound after washing with isopropyl alcohol, a correction is applied for the slight solubility of this addition compound, namely, 1 mg. per ml. of alcohol used. Florentin and Ruiz[147] suggest that the amine can be identified by the microscopical characteristics of its chloroaurate, chloroplatinate and best of all its silicotungstate. The formula of the latter is $SiO_2\,12WO_2 \cdot 4N(C_2H_4OH)_3$. The chlorometallic salts are soluble in water but may be crystallized from alcohol. The tungstate is a precipitate soluble in excess of the reagent.
